Background: Brain metastases significantly reduce the survival of cancer patients. However, detailed researches on the clinical manifestations and prognoses of patients with brain metastases are lacking. The aim of this study was to investigate the clinical features and prognostic factors of cancer patients with brain metastases.

Methods: A retrospective study was conducted on patients with brain metastases who were treated in our hospital between January 2014 and January 2019. Comparison of overall survival (OS) was performed by the Kaplan-Meier method. Multivariate Cox regression models was used to identify prognostic factors for OS.

Results: A total of 190 patients with complete data and Eastern Cooperative Oncology Group performance status (ECOG PS) 0–2 were enrolled. Patients with brain metastases from different primary sites had significantly different survival time ($P=0.001$). Patients who had a longer survival time included female patients (47.4%) (34 *vs.* 19 months, $P=0.002$), those with age <65 years (63.7%) (29 *vs.* 18 months, $P=0.002$), with ECOG 0 or 1 (44.2%) (32 *vs.* 21 months, $P=0.005$), with ≤ 3 brain lesions (61.1%) (29 *vs.* 20 months, $P=0.041$), and with small molecular targeted therapy (48.4%) (21 *vs.* 18 months, $P=0.006$). Furthermore, multivariate analysis revealed that female, age <65 years, ≤ 3 brain lesions, small molecular targeted therapy were independent favorable prognostic factors of OS.

Conclusions: Female, younger patients with ≤ 3 brain metastases predicted a better survival. To improve the poor outcomes of these patients, it is necessary to find clinically significant genetic abnormalities and administer the small molecular targeted therapy early in the course of treatment.

Keywords: Brain metastasis; cancer; prognostic factor; small molecular targeted therapy.

Introduction

Brain metastases significantly reduce the survival of cancer patients. Many patients have neurological symptoms when brain metastases are identified (1,2). Systemic chemotherapies for patients with brain metastases are limited because of the poor penetration of the blood-brain barrier (3,4). Many molecular targeted therapies

show intracranial effect (5,6), but most cancer patients are unsuitable for targeted therapy. Therefore, local therapies of brain metastases are important, including surgery, stereotactic radiosurgery (SRS) and whole brain radiotherapy (WBRT). SRS was reported to have the same local effect as surgery in select patients, and to have significantly less neurocognitive toxicity compared with WBRT (7,8). The treatment of brain metastases

should be highly tailored to individual patients decided by a multidisciplinary team. Lung and breast cancers are the most common primary tumors in patients with brain metastases (9,10).

Because of the low incidence of brain metastases in cancer patients (11,12), detailed researches on the clinical manifestation and prognoses of patients with brain metastases are currently lacking. The aim of this study was to investigate the clinical features and prognostic factors of cancer patients with brain metastases admitted to our hospital in the past 5 years.

Methods

Patients and methods

A retrospective study was conducted on cancer patients with brain metastases who were treated in our hospital between January 2014 and January 2019. All diagnoses of cancer patients were confirmed by histopathology. Those patients with ECOG >2 or hematological malignancies were excluded. A total of 190 cancer patients with brain metastases and complete clinical and follow-up data were included in our study. The collected data on patients included demographics, Eastern Cooperative Oncology Group performance status (ECOG PS), interval time from cancer diagnosis to brain metastases, primary tumor, symptom at the time of brain metastases, number of brain metastases, extracranial metastatic lesions (lung, liver or bone), systemic antitumor therapy, local therapy for brain metastases and survival time. Systemic antitumor therapies included cytotoxic chemotherapy, small molecular targeted therapy, hormone therapy and immunotherapy. Local therapies for brain metastases included surgery, SRS and WBRT. The study was approved by the ethics committee of our institute (2019KY024_KS001). Informed consent was not required because of the retrospective nature of the study.

Statistics

The clinical data were summarized as n (%) for categorical variables and median with range for continuous variables. Overall survival (OS) was calculated by the Kaplan-Meier method with the SPSS 17.0 statistics software (SPSS Inc., Chicago, IL, USA). OS was defined as the time from the date of brain metastases to the date of death or the end of the study (July 2019). Comparison of survival was performed using the log-rank test. Multivariate Cox regression models

were used to identify the prognostic factors for OS. A P value <0.05 was considered statistically significant.

Results

Patient characteristics

A total of 190 cancer patients with brain metastases were enrolled in this study. The clinical characteristics of these patients are shown in *Table 1*. One hundred patients (52.6%) were male and 90 (47.4%) were female. The median age of all patients was 60 years (range, 29–87 years), 121 (63.7%) were age <65 years and 69 (36.3%) were age ≥65 years. There were 84 (44.2%) patients with ECOG 0–1 and 106 (55.8%) patients with ECOG 2. The median interval time from cancer diagnosis to brain metastases was 10.5 months (range, 0–102 months), 80 patients (42.1%) had a metastasis interval ≤6 months and 110 (57.9%) had a metastasis interval >6 months. Brain metastases were primarily identified by MRI (178, 93.7%), but also by CT or PET/CT (6, 3.2%, respectively).

In the 190 patients with brain metastases, 123 (64.7%) patients were diagnosed with non-small cell lung cancer, 33 (17.4%) patients with small cell lung cancer, 16 (8.4%) patients with breast cancer, 4 patients with colorectal cancer, 3 patients with gastric cancer, 2 patients with liver, kidney, esophagus cancer, respectively, 1 patient with melanoma, ovarian, thymic, endometrial, apocrine cancer, respectively. At the diagnoses of brain metastases, 125 patients had no related symptom. In the symptomatic patients, headache (19, 10%) was the most common, followed by vertigo (13, 6.8%) and different degrees of hemiplegia (10, 5.3%).

The number of brain metastases was varied in patients. A total of 116 patients (61.1%) had 3 or less than 3 brain lesions, and 74 patients (38.9%) had more than 3 lesions. Extracranial lesion in lung, liver or bone in patients was analyzed. Seventy-four patients (38.9%) had none of the above extracranial lesions. One extracranial lesion was found in 80 patients (42.1%), and two or three lesions were found in 36 patients (18.9%). Ninety-two (48.4%) patients received small molecular targeted therapy, and the rest of the 98 patients (51.6%) did not. Local therapy for brain metastases was given in 147 patients (77.4%), not in the other 43 patients (22.6%).

Survival after brain metastases and prognostic factors of OS

The median follow-up time was 18 months (range, 3–92 months). Patients with brain metastases from different primary sites

16 months, $P=0.001$). Patients who had a longer survival time included female patients (34 *vs.* 19 months, $P=0.002$, *Figure 1*), those with age <65 years (29 *vs.* 18 months, $P=0.002$, *Figure 2*), with ECOG 0 or 1 (32 *vs.* 21 months, $P=0.005$), with ≤3 brain lesions (29 *vs.* 20 months, $P=0.041$, *Figure 3*), and with small molecular targeted therapy (21 *vs.* 18 months, $P=0.006$, *Figure 4*). Furthermore, multivariate analysis revealed that female, age <65 years, ≤3 brain lesions, small molecular targeted therapy were independent favorable prognostic factors of OS (*Table 2*).

Discussion

Cancer patients with brain metastases pose a clinical challenge and have a dismal prognosis (13,14). Information

had significantly different survival time (non-small cell lung cancer with 28 months *vs.* small cell lung cancer with 16 months *vs.* breast cancer with 53 months *vs.* others

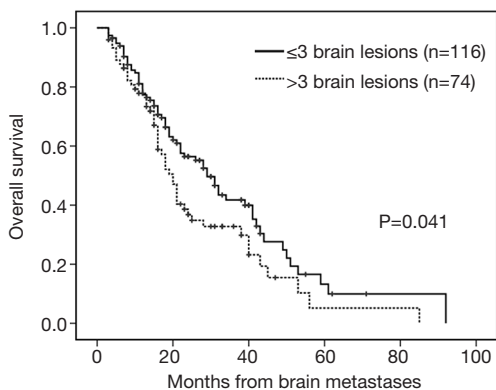

Figure 3 OS of patients: ≤3 brain metastases vs. >3 brain metastases. OS, overall survival.

about clinical characteristics and prognostic factors is crucial to the diagnosis, therapy and prognosis of patients with brain metastases (1). In the current study, the clinical features and prognostic factors of 190 patients with brain

metastases were evaluated.

In this cohort, both gender and age were independent prognostic factors of OS. Female patients had a longer survival time, which could be explained by better prognosis of breast cancer patients. In addition, 60 percent of female patients (54 of 90 patients) received small molecular targeted therapy, while only 38 percent of male patients (38 of 100 patients) did. Rastogi *et al.* reported that survival was significantly improved in female patients (15). Young patients had a favorable prognosis, which was in line with other studies (16,17).

Patients with good ECOG performance status have been reported to have better outcomes (16,18). Similarly, in our study, patients with good performance status had a longer survival. However, no significant difference was found after multivariate analysis. This is perhaps because all patients included in our study were ECOG PS ≤2, and there were no major differences in the intensity of treatment for these patients. Cacho-Diaz *et al.* reported that some symptoms were associated with poor outcomes in patients with brain metastases (1). In our study, there was no survival difference between patients with or without symptom associated with brain metastases at the diagnoses. Most of the patients in our study were found to have brain metastases at the regular screening in the absence of symptom, in contrast with the work of Cacho-Diaz *et al.*, which found that the majority of patients had over one symptom at the time of diagnosis.

The prognoses in patients with brain metastases were significantly different depending on the type of primary cancer (5,19). In our study, the best survival was observed in patients with breast cancer, followed by non-small cell lung cancer. Both of the tumors had more therapeutic

OS, overall survival; BM, brain metastases.

modality options and were more sensitive to treatment. The interval time from cancer diagnosis to brain metastases was varied from 0 to 102 months. No survival difference was observed between the patients with less or more than a 6-month interval. This suggested that the diagnosis of brain metastases indicated a very poor prognoses irrespective of the interval time.

Patients with brain oligometastasis are believed to have a better survival than those with multiple brain metastases (1,15). In our study, patients with ≤ 3 brain metastatic lesions also had a favorable survival, which was an independent prognostic factor in the multivariate analysis. With regard to extracranial lesion of lung, liver or bone, there was no significant difference in survival correlated with various numbers of extracranial lesions. The probable cause here was that brain metastasis was a markedly poor prognostic factor regardless of extracranial lesion. However, a report from Ekici showed that patients with extracranial lesion had a shorter survival than those with only brain metastasis (18). More studies are needed to elucidate the clinical significances of extracranial lesions.

Effective local treatments for brain metastases include surgery, SRS and WBRT (20,21). In our study, patients who received local therapy for brain metastases received no survival benefit. Local therapies may be useful of yielding a local control and relieving the symptom of patients with brain metastases, but in our cohort, they did not improve survival time. Small molecular targeted drugs can penetrate the blood-brain barrier and have a better therapeutic effect than systemic chemotherapy (5,22). This may explain that patients given with small molecular targeted therapy had a longer survival and the targeted therapy was a positive independent prognostic factor in our study. This finding was in good agreement with the results of a study by Füreder *et al.* (23).

Conclusions

In conclusion, the favorable independent prognostic factors for patients with brain metastases were female, younger age, fewer brain metastases and small molecular targeted therapy. Female, younger patients with less than or equal to 3 brain metastases predicted a better survival. To improve the poor outcomes of patients with brain metastases, it is necessary to find clinically significant genetic abnormalities whenever possible and administer the small molecular targeted therapy early in the course of treatment.
