**Abstract:** Metastasis to breast from ovarian cancer is very rare, and it is very difficult to distinguish the primary breast cancer from the secondary one. In our case, a 61-year-old woman presented to the hospital with complaints of lower abdominal pain and distention. Abdominal-pelvic computed tomography (CT) imaging revealed a solid ovarian cystic tumor with numerable ascites in the abdominal cavity and disseminated peritoneal carcinomatosis. To confirm the presence of metastasis in other organs, a preoperative imaging studies including chest CT was performed. Chest CT imaging revealed an enlargement of both the axillary lymph nodes (r/o metastatic lymphadenopathy) and breast imaging studies (breast sonography and mammography) revealed masses penetrated the pectoralis major muscle in the left breast and metastatic lymphadenopathy in Lt axilla. The core needle biopsy result of breast lesion showed unknown origin carcinoma with micropapillary features and no psammoma bodies. So, we could not distinguish primary breast cancer and breast metastasis from ovarian cancer because breast metastasis from ovary could be contained psammoma bodies, generally. Although the possibility of primary breast cancer could not be ruled out absolutely, the neoadjuvant chemotherapy included Paclitaxel and Carboplatin is known to be effective for both breast and ovarian cancer. So after neoadjuvant chemotherapy, mastectomy concurrently with ovarian cancer surgery was performed. The histopathologic features of the ovaries and breast were similar and psammoma bodies also could be observed, which were not detected in previous core needle biopsied specimen. And lymph nodes from the breast and the ovaries also showed consistent findings. Combined with histopathologic report and medical records, the final diagnosis confirmed as a metastasis of ovarian cancer to breast. After surgery, the patient has continued with metastatic ovarian cancer specific treatment. Breast metastatic tumors must be distinguished from primary breast tumors to avoid any unnecessary surgery. It might be difficult to diagnosis precisely by using only core needle biopsy because of inadequate specimen volume. Although surgical resection may be effective for both diagnosis and palliative treatment, further studies focused on less invasive biopsy are needed for exact histopathological diagnosis.

## Introduction

Breast metastasis from other solid organs (ovary, cervix, and other pelvic cavity organs) are very rare. Metastatic breast cancer accounts for only approximately 0.33–6.3% of all breast cancers, and then almost cases also are from melanomas, sarcomas, lung cancer, and renal carcinomas (1,2). Because imaging studies (mammography, ultrasonographic images) have a low specificity, it is hard to distinguish the primary breast cancer from secondary breast cancer using by imaging studies alone. In comparison with primary breast cancer, metastatic or secondary breast cancer has a relatively poorer prognosis (3). Making an adequate therapeutic plan is also very difficult. So that treatment plan of breast metastasis focuses on tumor management by using systemic chemotherapy to avoid unnecessary surgery.

Especially, metastases to the breast from ovarian cancer are rare, and only a few cases have been reported globally since 1907, when the first case was reported (4,5). This report describes our experience with a patient who presented with metastasis to the breast from ovarian cancer. Usually, metastases to breast detected within 2 years from the initial diagnosis of primary ovarian cancer (6). But, our patient diagnosed with primary ovarian cancer and metastasis to the breast concurrently.

In addition, to the best of our knowledge, there are only a few reports for breast metastasis from ovary. But this case report that existing concurrently both breast metastasis from ovary and ovarian cancer when initial diagnosis might be the first. And it is strengths for our case report.

We present the following case in accordance with the CARE reporting checklist (available at <http://dx.doi.org/10.21037/gs-20-640>).

## Case presentation

A 61-year-old woman presented to the hospital with complaints of lower abdominal pain and distention in august 2017. According to the Patient's family history, the older brother had gastric cancer. The patient had never been diagnosed with ovarian or breast cancer before.

Abdominal-pelvic computed tomography (CT) imaging revealed both a solid ovarian cystic tumor with numerable ascites in the abdominal cavity and disseminated peritoneal carcinomatosis (*Figure 1*). To confirm the presence of metastatic disease in other organs, a preoperative chest CT scanning was performed. This revealed an enlargement of both the axillary lymph nodes (r/o metastatic

lymphadenopathy). The radiologist recommended further breast evaluation. Breast ultrasound and mammography revealed a mass near the retro mammary space in the left breast. This mass penetrated the pectoralis major muscle and metastatic lymphadenopathy was noted in both axillas (*Figure 2A,B*).

The core needle biopsy from breast lesion showed unknown originated carcinoma with micropapillary features with no psammoma body (*Figure 3A*). Immunohistochemical analysis of the tumor revealed the mass to be estrogen receptor (ER) negative, progesterone receptor (PR) positive (Allred score 5), human epidermal growth factor 2 (HER2) negative (score 0), p53 protein positive, Wilms' tumor 1 (WT-1) positive, paired box gene 8 (PAX8) positive, GATA binding protein 3 (GATA3) negative, and with Ki-67 index of 80%.

Based on the histologic features of micropapillary formation with positive PR immunostaining, the possibility of primary breast cancer could not be ruled out absolutely. But, this might suggested the possibility of metastatic carcinoma from the ovary, rather than primary micropapillary carcinoma of the breast, considering ovarian cancer history.

The patient underwent neoadjuvant chemotherapy (Paclitaxel 175 mg/BSA, Carboplatin 5 AUC, every three weeks for three cycles) prior to surgery. This chemotherapy is known to be effective for both breast and ovarian cancer. Under general anesthesia, total abdominal hysterectomy + bilateral salpingo-oophorectomy (TAH/BSO), low anterior resection (LAR) were performed in November 2017. And radical total mastectomy also performed for precise diagnosis and palliative purpose.

The histologic features of the right and left ovaries showed high grade serous carcinomas, measuring 8.8 cm × 7.4 cm and 4.8 cm × 3.7 cm in size, respectively (*Figure 3B*). Most of the ovary was replaced by a solid tumor mass with cystic area. The resected breast showed multiple tumor masses, ranging from 0.3 to 2.0 cm in size. The histologic features of the ovaries and right breast were similar to each other, with micropapillae and psammoma bodies, which were not detected in previous core needle biopsied specimen (*Figure 3C*). Immunostainings for PR, p53, WT-1, and PAX8 were positive; however, ER and GATA3 were negative, and Ki-67 index was 80%. Lymph nodes from the breast and the ovaries, rectum, and omentum showed consistent findings. The final diagnosis was high grade serous carcinoma of the ovaries, and metastases to the left breast and rectum, including the regional lymph nodes.

Adjuvant chemotherapy was administered (Paclitaxel 175 mg/BSA, Carboplatin 5 AUC, every three weeks for six cycles) after surgery. We checked for side effects at each chemotherapy cycle. There were mild nausea, dyspnea and moderate tingling in both hand, foot. But the patient could tolerate it.

Positron emission tomography/computed tomography (PET/CT) was conducted In June 2018. This imaging showed residual tumor; hence, palliative chemotherapy (doxorubicin 40 mg/BSA, bevacizumab 10 mg/kg) was administered. After 4 cycles of palliative treatment, we discussed about prognosis with patient and she refused more treatment. Follow up has been lost since September 2018.

All procedures performed in studies involving human participants were in accordance with the ethical standards of

the institutional and/or national research committee(s) and with the Helsinki Declaration (as revised in 2013). Written informed consent was obtained from the patient. This study was approved by the Institutional Review Board (IRB) of the Pusan National University Yangsan Hospital (IRB No. 05-2020-153).

## Discussion

Breast cancer is the most frequently diagnosed primary cancer in women. Breast cancer almost always originates from the mammary glands, and most metastatic breast cancers originate from the contralateral breast (3). Advanced ovarian cancer typically demonstrates peritoneal dissemination or lymph node metastases in the abdominal cavity; distant metastases are rare. However, ovarian cancer occasionally metastasizes to the liver, pleura, or lung, and the prognosis of ovarian cancer patients with distant metastasis is poor (7).

Primary gynecological cancers that metastasize to the breast are rare. The overall incidence of primary gynecologic tumor metastases to the breast was 0.17%, and among all the breast cancer cases, only 0.07% are mammary metastases from primary ovarian tumors (8).

Distinguishing primary breast cancer from metastatic breast cancer is very difficult because imaging findings are not specific and diagnostic (9). Generally, almost breast metastases are detected by mammography, and typically consist of a round and clear-margined mass. There are seldom unclear margins, and microlobulated

**Figure 1** Abdominal-pelvic CT images of the ovarian cancer; note the larger, bilateral ovarian masses and ascites.

**Figure 2** Radiologic findings. (A) Metastatic lymphadenopathy at mammography; Lt. axilla with multiple enlarged lymph nodes; (B) ultrasonography image revealing a regular-bordered round or oval shaped hypoechoic lesion.

**Figure 3** Radiologic findings. (A) Histologic features of the core needle biopsy of the breast tissue showing invasive carcinoma with micropapillary features without psammoma body (H&E stain,  $\times 100$ ). (B) Microscopic features of the right ovary. High grade carcinoma with micropapillary features and tumor infiltrating lymphocytes (TIL) and psammoma bodies (H&E stain,  $\times 200$ ); (C) (left) Immunohistochemical staining for PAX-8 ( $\times 100$ ) and (right) WT-1 ( $\times 100$ ) showed strong and diffuse positivity.

shaped masses are rare. Furthermore, there is generally no evidence of microcalcification or architectural distortion on mammography (2). Calcifications are not usually present in patients with metastases to breast from ovarian cancer because of the presence of psammomatous bodies (10-13) and then most lesions of this type often founded in the subcutaneous layer of the breast mammary gland because of the rich blood supply to this region and axillary lymph node metastases are seldom revealed, compared with primary breast cancer (14).

The treatment and prognosis of primary breast cancer and metastasis to the breast from ovary are very different. Breast metastasis from ovarian cancer may disseminate widely and it is associated with a poor prognosis. The mean-survival time was previously reported to range from 13 days to 3.5 years (15-17). However, many patients have survived in less than one year after the diagnosis. Statistics on prognosis show that the 1-year survival rate is about 40% (12) the treatment of choice for metastasis from ovarian cancer is generalized systemic chemotherapy

with appropriate chemotherapeutic agents (platinum based chemotherapy) and cytoreductive surgery to reduce tumor burden, whereas surgical management should be considered diagnostic and palliative (NCCN guidelines version 1.2020).

If the metastatic breast lesion is not larger or positioned in the deep tissue layers, and if there are no symptoms, palliative surgery also should not be considered. If only patients have a symptom, a mastectomy should be performed for only palliative purposes (18).

For these reasons, accurate and precise diagnosis is very necessary to make a treatment plan. The treatment plan should be determined considering combined data from an accurate medical history, physical examination, imaging studies analyses and definitive biopsy results. Therefore, surgeons could not perform unnecessary mastectomy.

When initial diagnosis, imaging studies revealed both ovary cancer and metastasis to breast concurrently in our case. There are other two possibilities which secondary ovarian cancer and primary breast cancer and double primary breast cancer and ovarian cancer as co-morbidities.

Differentiating between primary and secondary ovarian cancer can be a difficult task. In hereditary conditions breast malignancies and primary ovarian cancer often coexist. BRCA1 and BRCA2 mutations are responsible for the concomitant occurrence of these two cancer types. Specifically, women with BRCA1 alterations have a high risk of developing breast (85%) and ovarian (40–60%) cancer, whilst women with BRCA2 mutations have a similar risk of breast cancer as with BRCA1 mutations and 15–30% probability of developing ovarian cancer (19,20). The bare suggestion that only core needle biopsy results, it could not be possible to distinguish primary cancer from secondary cancer. Although the possibility of primary breast cancer could not be ruled out absolutely, we decided that the possibility of metastatic carcinoma from the ovary is higher than the one of primary breast cancer considering as a history of ovarian cancer. Metastatic breast cancer must be excluded by appropriate histopathological examination. Although the resection of the breast lesion does not positively affect the prognosis for metastasis to breast from ovary, it appears to be important to have an adequate specimen in order to establish the precise diagnosis. Follow above, the most common histological type of breast metastases from ovary would be serous papillary carcinoma contained psammoma bodies (8). But in our case, the core needle biopsy result of breast lesion revealed a micropapillary lesion with no psammoma bodies. It makes us unable to make an accurate diagnosis before surgery. So, radical mastectomy concurrently with ovarian cancer surgery was performed. This surgical intervention was very effective method for both treatment and diagnosis, because our patient have complained pain for breast lesion also and the specimen from mastectomy can present more precise and exact histopathological results for diagnosis.

In conclusion, this is the very rare case for breast metastasis from ovary and ovarian cancer concurrently when initial diagnosis. But if there are breast lesions concurrently with ovarian cancer, possibilities of metastasis to breast from ovary might be considered in patients with an ovarian cancer. It might be difficult to diagnosis precisely using only core needle biopsy because of inadequate specimen volume.

Further studies focused on less invasive biopsy for exact histopathological diagnosis are needed for accurate differentiation to avoid unnecessary surgery.
