#### Abstract

Background: The Hong Kong $\alpha \alpha$ (HK $\alpha \alpha$ ) allele is a complex structural rearrangement of the $\alpha$-globin gene containing $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {ant }}{ }^{4.2}$ crossover junctions. Clinically, individuals carrying the HK $\alpha \alpha$ allele are often misdiagnosed or missed using conventional thalassemia gene detection technology. This study aims to identify and validate different HK $\alpha \alpha$ thalassemia subtypes using third-generation sequencing (TGS) technology. Methods: Between January 2015 and June 2021, 32 patients suspected of having HK $\alpha \alpha$ thalassemia were included in this study. Genomic DNA was extracted, and gap-polymerase chain reaction (PCR), two-round nested PCR, multiplex ligation-dependent probe amplification (MLPA), and TGS were used for thalassemia gene detection. Results: The results of $H K \alpha \alpha / \alpha \alpha$ and $H K \alpha \alpha /-\alpha^{3.7}$ were similar to $-\alpha^{3.7} / \alpha \alpha$ using the gap-PCR method. Tworound nested PCR could be used to verify the HK $\alpha \alpha$ gene, but could not distinguish the subtypes of HKa $\alpha$ thalassemia. The MLPA assay was used to detect the change in the copy number of the $\alpha$-globin gene, but it could not determine whether $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {anti }}{ }^{4.2}$ were in cis or in trans. Long-read TGS technology could accurately detect the HK $\alpha \alpha$ allele and distinguish the genotypes of $H K \alpha \alpha / \alpha \alpha, H K \alpha \alpha /-\alpha^{3.7}, H K \alpha \alpha /-\alpha^{4.2}$, and $H K \alpha \alpha /--{ }^{\text {SEA }}$ without pedigree analysis. The contiguous sequence of the HK $\alpha \alpha$ allele was detected using the TGS approach. This study also demonstrated that individuals with HK $\alpha \alpha / \alpha \alpha$ and $\beta^{\mathrm{N}} / \beta^{\mathrm{N}}$ genotypes tended to have normal hematological phenotypes. Conclusions: Long-read TGS is a reliable and efficient approach for accurate detection of HK $\alpha \alpha$ thalassemia, which can be widely used in clinical practice. Accurate molecular diagnosis of HK $\alpha \alpha$ thalassemia will benefit clinical genetic counseling and prenatal diagnosis.

## Introduction

Thalassemia is one of the most common genetic diseases worldwide, characterized by a variable degree of chronic progressive hemolytic anemia (1). According to hemoglobin chain damage, thalassemia can be categorized into $\alpha-, \beta-$,
$\delta$-, $\gamma$-, $\delta \beta$-, and $\varepsilon \gamma \delta \beta$-thalassemias (2). Thalassemia is highly prevalent in the Mediterranean, central Asia, Middle East, India, and southern China (3). Of all thalassemia types, $\alpha$-thalassemia is the most widely distributed and is common in Southeast Asia and China $(2,4,5)$. This thalassemia type
is caused by disturbances in $\alpha$-globin chain synthesis. The gene for synthesizing $\alpha$-like globin peptides is located on 16 p13.3. Normally, with $2 \alpha$-globin genes on each chromosome, an individual would have 2 pairs of $\alpha$-globin genes, defined as $\alpha \alpha / \alpha \alpha$. In the $\alpha$-globin gene cluster, HBA1 and HBA2 have a high degree of homology (homologous X, $\mathrm{Y}, \mathrm{Z}$ regions), which can lead to unequal crossover.

The most common type of $\alpha$-thalassemia is caused by deletions of different lengths in the $\alpha$-globin genes, with $-\alpha^{3.7}$ and $-\alpha^{4.2}$ variants being the more common forms $(5,6)$. The reciprocal recombination between $Z$ segments during meiosis leads to the $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {and }}{ }^{3.7}$ chromosomes. The crossover between impaired X-boxes leads to $-\alpha^{4.2}$ and $\alpha \alpha \alpha^{\text {ani }}$ ${ }^{4.2}$ chromosomes (4). On this basis, further misalignment and unequal crossover of homologous regions in $\alpha$-globin gene clusters may generate other special crossover events. Wang et al. (7) first reported a complex structural rearrangement containing both $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {and }}{ }^{4.2}$ crossover junctions on the same chromosome, designated as Hong Konga (HKa人). The HK $\alpha \alpha$ allele contains neither a single gene deletion nor triplication. Several studies have reported that individuals with the HKac allele present with normal hematological phenotype (8-10). Individuals with compound heterozygote of HK $\alpha \alpha$ and -- ${ }^{\text {SEA }}$ showed a typical $\alpha$-thalassemia trait (11). Although the HK $\alpha \alpha$ allele does not have any deleterious effect on the clinical phenotype of carriers, genetic testing of the HKa allele has important implications for genetic counseling and prenatal diagnosis. Because routine molecular testing reagents for deletional $\alpha$-thalassemia cannot directly detect $\alpha \alpha \alpha^{\text {ani }}{ }^{4.2}$ and $\alpha \alpha \alpha^{\text {and }}{ }^{3.7}$, it is easy to misjudge $H K \alpha \alpha / \alpha \alpha$ or anti-HK $\alpha \alpha / \alpha \alpha$ as $-\alpha^{3.7} / \alpha \alpha$ or $-\alpha^{4.2} /$ $\alpha \alpha$. Such misjudgments may lead to incorrect genetic counseling by clinical geneticists and may lead to incorrect prenatal diagnoses for patients.

In recent years, researchers have developed several molecular detection methods to detect HK $\alpha \alpha$ thalassemia. Wang et al. (7) first developed a two-round nested PCR strategy to detect the presence of the novel HK $\alpha \alpha$ allele. Long et al. (12) designed a qPCR system to screen for $\alpha \alpha \alpha^{\text {anti } 3.7}, \alpha \alpha \alpha^{\text {ant } 4.2}$, and HK $\alpha \alpha$ genes. Huang et al. (13) also proposed that PCR-based multicolor melting curve analysis could identify HK $\alpha \alpha$-derived genotypes. However, these methods have certain limitations.

In clinical practice, the use of conventional thalassemia gene analysis methods to detect the HK $\alpha \alpha$ allele presents certain challenges. In the $\alpha$-globin gene cluster, HBA1 and HBA2 are highly homologous, and the fragment of the homologous region is relatively long, thus the sequence
detection of highly homologous regions of $\alpha$-globin genes remains a major problem for short-read technology. Long reads can resolve tandem repeats and complex structural rearrangements (14). Long-molecule sequencing (LMS) is the dominant feature of third-generation sequencing (TGS). Studies have proven that the LMS-based PacBio TGS platform is an accurate test with potential clinical utility as an alternative for screening thalassemia carriers $(15,16)$. In this study, TGS based on single-molecule real-time (SMRT) technology was performed to detect the HK $\alpha \alpha$ allele, and this was compared with the other molecular techniques. We present the following article in accordance with the MDAR reporting checklist (available at https://atm.amegroups. com/article/view/10.21037/atm-22-4309/rc).

## Methods

## Patients

Between January 2015 and June 2021, 32 individuals suspected of having HK $\alpha \alpha$ thalassemia at the Affiliated Hospital of Guilin Medical University (Guilin, People's Republic of China) were included in the study. Fresh peripheral blood samples were collected and then stored at $4^{\circ} \mathrm{C}$. The basic information, routine hematology examination, and hemoglobin electrophoresis of all patients were collected from medical records. The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The study was approved by the Ethics Committee of the Affiliated Hospital of Guilin Medical University (No. 2020GZRLL-46) and informed consent was obtained from all individual participants.

## DNA extraction

Genomic DNA was extracted using the Nucleic Acid Extraction System (Zeesan Biotech, Xiamen, China). DNA concentration and quality were determined by the NanoDrop 2000 spectrophotometer. DNA concentration ranged from 40 to $60 \mathrm{ng} / \mu \mathrm{L}$, and the A260/A280 ranged from 1.80 to 1.88 . DNA was stored at $-20^{\circ} \mathrm{C}$ in a freezer until use.

## Gap-PCR

Gap-PCR and agarose gel electrophoresis for $-\alpha^{3.7},-\alpha^{4.2}$, $--{ }^{\text {SEA }}$, and -- ${ }^{\text {THAI }}$ were performed using a commercial deletional $\alpha$-thalassemia gene detection kit (Yishengtang

Figure 1 Molecular detection of HK $\alpha \alpha$ alleles by gap-PCR. HK $\alpha$, Hong Kong $\alpha \alpha$; PCR, polymerase chain reaction.

Biological Products Co. Ltd., Shenzhen, China). The two-round nested PCR was performed to determine the presence of the HKad allele as our previously described methods (10).

## PCR-reverse dot blot (RDB) assay

PCR-RDB analysis was used to detect 3 common point mutations in $\alpha$-thalassemia ( $\alpha^{\mathrm{CS}} \alpha, \alpha^{\mathrm{QS}} \alpha$, and $\alpha^{\mathrm{WS}} \alpha$ ) and 17 -point mutations in $\beta$-thalassemia using a commercial kit (Yaneng BioSciences Co., Shenzhen, China).

## Multiplex ligation-dependent probe amplification (MLPA) assay

MLPA was used to detect copy number variations of $\alpha$-globin genes. The MLPA-PCR reaction was performed in a $50 ~ \mu \mathrm{~L}$ reaction system with the SALSA MLPA Probemix P140-C1 kit (MRC-Holland, Amsterdam, Netherlands). In short, the thermocycler program for the MLPA reaction was as follows: (I) DNA denaturation; (II) hybridization reaction; (III) ligation reaction; and (IV) PCR reaction. The PCR products were analyzed using the 3500Dx Genetic Analyzer (Applied Biosystems, Foster City, CA, USA).

## TGS and data analysis

The long-read sequencing-based comprehensive analysis of thalassemia alleles (CATSA) assay was carried out similarly as previously described (16). In brief, genomic DNA was extracted and subjected to multiplex long-range PCR with primers covering the full length of the $H B A$ and $H B B$ genes and the majority of known structural variations (SVs). Endrepair and ligation reactions were added to PCR amplicons with unique PacBio barcoded adaptors, and the exonucleases were added to digest failed ligation products to obtain an
individual prelibrary for each sample. After purification and quantification, the individual prelibrary was pooled by equal mass and converted to an SMRT dumbbell library with the Sequel Binding and Internal Ctrl Kit 3.0 (Pacific Biosciences, Menlo Park, CA) and sequenced on the Sequel II platform (Pacific Biosciences) for 30 h . High fidelity circular consensus sequencing (CCS) reads were generated from raw subreads, demultiplexed by barcodes, and aligned to genome build hg38 in the SMRT Link system (Pacific Biosciences). Single-nucleotide variations (SNVs) and indels were called by FreeBayes1.3.4 (Biomatters, Inc., San Diego, CA), and SVs were called according to read length. SNVs, indels, and SVs were annotated according to HbVar, Ithanet, and LOVD databases. CCS reads generated by CATSA were displayed in the Integrative Genomics Viewer (IGV) to show different variants.

## Results

## HKaa allele detection by gap-PCR and two-round nested PCR

By using the deletional $\alpha$-thalassemia gene detection kit, the 32 samples were detected by the gap-PCR method. The test results showed that individuals with $-\alpha^{3.7} / \alpha \alpha$, HK $\alpha \alpha / \alpha \alpha$, and HK $\alpha \alpha /-\alpha^{3.7}$ were positive for the $-\alpha^{3.7}$ allele and the normal allele (Figure 1). The electrophoresis bands of HK $\alpha \alpha / \alpha \alpha$ and $H K \alpha \alpha /-\alpha^{3.7}$ were similar to $-\alpha^{3.7} / \alpha \alpha$. However, for HK $\alpha \alpha / \alpha \alpha$, the electrophoresis band of the $-\alpha^{3.7}$ allele was significantly weaker than that of the normal allele. Individuals with HK $\alpha \alpha /-\alpha^{4.2}$ were positive for the $-\alpha^{3.7}$ allele, $-\alpha^{4.2}$ allele, and the normal allele, while individuals with HK $\alpha \alpha /$ _- ${ }^{\text {SEA }}$ were positive for the $-\alpha^{3.7}$ allele, $--{ }^{\text {SEA }}$ allele, and the normal allele (Figure 1). Two-round nested PCR was performed to confirm the HKa allele, which was published by our research group in previous papers (10).

## HKaa allele detection by the MLPA assay

The MLPA assay can be used to detect the deletion/ duplication of large fragments in the $H B A$ gene region. The copy number of $\alpha$-globin genes in individuals with the HKau allele was detected using MLPA (Figure 2). For the $H K \alpha \alpha / \alpha \alpha$ genotype, the probe signals in the $-\alpha^{3.7}$ region were decreased (ratio 0.5), while the probe signals in the $-\alpha^{4.2}$ region were increased (ratio 1.5) (Figure 2A). For the HK $\alpha \alpha /-\alpha^{3.7}$ genotype, the probe signals in the $-\alpha^{3.7}$ region were completely absent (ratio 0 ), while the probe signals

Figure 2 Molecular detection of HK $\alpha \alpha$ alleles by MLPA. (A) HK $\alpha \alpha / \alpha \alpha$. (B) HK $\alpha \alpha /-\alpha^{3.7}$. (C) HK $\alpha \alpha /-\alpha^{4.2}$. (D) HK $\alpha \alpha /-{ }^{\text {EEA }}$. The $x$-axis represents MLPA probe location (hg18). The y-axis represents the final ratio. HKa $\alpha$, Hong Konga ; MLPA, multiplex ligation-dependent probe amplification.
in the $-\alpha^{4.2}$ region were increased (ratio 1.5) (Figure 2B). In samples with $H K \alpha \alpha /-\alpha^{4.2}$, only the probe signals in the $-\alpha^{3.7}$ region were reduced, which would cause the sample to be misdiagnosed as $-\alpha^{3.7} / \alpha \alpha$ (Figure $2 C$ ). In samples with $H K \alpha \alpha /--{ }^{\text {SEA }}$, the signal ratio of the probe in the HBA gene region was the result of the sum of $-\alpha^{3.7},--{ }^{\text {SEA }}$, and $\alpha \alpha \alpha^{\text {anti } 4.2}$ (Figure 2D). It should be noted that a single MLPA test is not sufficient to identify the HK $\alpha \alpha$ allele.

## HKaん allele detection by TGS

TGS based on long-read SMRT technology was used to detect the complex structural rearrangements of $\alpha$-globin genes. The results of TGS technology for individuals with the HK $\alpha \alpha$ allele are shown in Figure 3. Recombinant SVs
involving $-\alpha^{3.7},-\alpha^{4.2},-{ }^{\text {SEA }}$, and HK $\alpha \alpha$ variants on 2 DNA strands were well identified. The TGS technology could directly detect the $\mathrm{HK} \alpha \alpha$ allele and correctly distinguish various types of genotypes. In addition, 2 rare variants in $H B B[-50(\mathrm{G}>\mathrm{A})$ and $-198 \mathrm{~A}>\mathrm{G}]$ were discovered in $2 \mathrm{HK} \alpha \alpha$ samples by the TGS assay.

In this study, the contiguous sequence of the HKa allele was detected using long reads of TGS technology. Sequence data are provided in the Appendix 1.

## Hematological characteristics of individuals with the HKa allele

The hematological characteristics of individuals with the HKa allele are shown in Table 1. Most individuals with

Figure 3 Molecular detection of HK $\alpha \alpha$ alleles by TGS. (A) HK $\alpha \alpha / \alpha \alpha$. (B) HK $\alpha \alpha /-\alpha^{3.7}$. (C) HK $\alpha \alpha /-\alpha^{4.2}$. (D) HK $\left.\alpha \alpha /-\right]^{\text {SEA }}$. HK $\alpha \alpha$, Hong Kongad; TGS, third-generation sequencing.

HK $\alpha \alpha / \alpha \alpha$ and $\beta^{N} / \beta^{N}$ genotypes had normal hematological phenotypes. Only 2 of 18 individuals with HK $\alpha \alpha / \alpha \alpha$ and $\beta^{\mathrm{N}}$ / $\beta^{\mathrm{N}}$ genotypes manifested obvious microcytic hypochromic anemia, which might be related to the combination of iron deficiency. Individuals with $\mathrm{HK} \alpha \alpha /-\alpha^{4.2}$ or $\mathrm{HK} \alpha \alpha / \alpha^{\mathrm{WS}} \alpha$ genotypes showed silent $\alpha$-thalassemia, while individuals with the $\mathrm{HK} \alpha \alpha /$-- $^{\text {SEA }}$ genotype showed mild $\alpha$-thalassemia. $H K \alpha \alpha / \alpha \alpha$ and $H K \alpha \alpha /-\alpha^{3.7}$ combined with the $H B B$ variant displayed obvious hematological features of $\beta$-thalassemia (Table 1).

## Discussion

HK $\alpha \alpha$ is a rare complex crossover event of the a-globin gene cluster, containing a cis-recombination of $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {anti } 4.2}$. Research has reported that the carrier rates of the HKa $\alpha$ allele ranged from $0.04 \%$ to $0.33 \%$ in southern China (8,12,17-20). Furthermore, the frequency of HK $\alpha \alpha$ ranged from $2.27 \%$ to $8.81 \%$ in $-\alpha^{3.7}$ carriers $(9,20,21)$. The carrying rate of $\mathrm{HK} \alpha \alpha$ is significantly different in different regions, which might be related to different detection methods and ancestral effects of population distribution.

HK $\alpha \alpha$ is a rearrangement of the a-globin gene. As shown in Figure 3, Integrative Genomics Viewer plots of HKa人 allele reveal that there is virtually no deletion or duplication of the gene. Therefore, individuals with $\mathrm{HK} \alpha \alpha / \alpha \alpha$ presented a normal hematological phenotype, and this structural variant does not aggravate the clinical phenotype of patients even when combined with other $\alpha / \beta$-mutations, which is consistent with previously reported results ( $7,8,11,19,21$ ). Although the carrier rate of the HK $\alpha \alpha$ allele is low and the carriers do not have any clinical manifestations, its molecular diagnosis has important clinical significance.

At present, DNA testing is a regular part of the management of thalassemia. In clinical practice, the most common DNA testing methods for thalassemia are gapPCR and PCR-RDB analysis with hot-spot mutation detection kits. The gap-PCR-based deletional $\alpha$-thalassemia gene detection kit used in clinical practice cannot detect triplication, which will result in missed diagnosis or misdiagnosis of the HK $\alpha \alpha$ allele. In this study, the results of gap-PCR showed that electrophoresis bands of HK $\alpha \alpha / \alpha \alpha$ and $\mathrm{HK} \alpha \alpha /-\alpha^{3.7}$ were the same as $-\alpha^{3.7} / \alpha \alpha$, resulting in both $H K \alpha \alpha / \alpha \alpha$ and $H K \alpha \alpha /-\alpha^{3.7}$ being misdiagnosed as $-\alpha^{3.7} / \alpha \alpha$.

RBC, red blood cell; Hb , hemoglobin; MCV, mean corpuscular volume; MCH , mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; $\mathrm{HbA}_{2}$, hemoglobin $\mathrm{A}_{2}$.

Such misjudgments can lead clinicians to provide incorrect genetic counseling and prenatal diagnosis. Furthermore, $\alpha^{0}$-thalassemia coinherited with $-\alpha^{3.7}\left(--/-\alpha^{3.7}\right)$ can result in hemoglobin $\mathrm{H}(\mathrm{HbH})$ disease, while $\alpha^{0}$-thalassemia coinherited with the HKad allele (--/HK $\alpha \alpha$ ) presents as mild $\alpha$-thalassemia.

The MLPA technique is also a common clinical method for detecting copy number changes when rare variations in the $\alpha$-globin gene are suspected. Most of the deletion subtypes of $\alpha$-thalassemia can be detected by MLPA, including $-\alpha^{3.7},-\alpha^{4.2},--{ }^{\text {SEA }},-{ }^{\text {THAI }},-{ }^{\text {FIL }}$, and $\left(-\alpha^{20.5}\right)$, among others. The $\alpha$-triplication ( $\alpha \alpha \alpha^{\text {anti } 3.7}$ and $\alpha \alpha \alpha^{\text {ant } 4.2}$ ) can also be detected by MLPA with the P140 Probemix. However, copy number variations of the $H B A$ gene detected by MLPA should be confirmed using a different technique. As shown in Figure 2A, both $-\alpha^{3.7}$ and $\alpha \alpha \alpha^{\text {and } 4.2}$ were detected in a single sample, but it was impossible to determine whether the genotype was an HK $\alpha \alpha / \alpha \alpha$ or $\alpha \alpha \alpha^{\text {ant }}{ }^{4.2} /-\alpha^{3.7}$ compound heterozygous mutation. Additional experiments or pedigree analysis are required to determine the correct genotype, as genetic counseling for $\mathrm{HK} \alpha \alpha / \alpha \alpha$ and $\alpha \alpha \alpha^{\text {anti }} 4.2 /-\alpha^{3.7}$ compound heterozygous mutation is completely different. In the case of $\alpha \alpha \alpha^{\text {ant }} 4.2 /-\alpha^{3.7}$ compound heterozygosity, inheritance to the offspring could only be $\alpha \alpha^{\text {amit }}{ }^{4.2}$ or $-\alpha^{3.7}$. In addition to compound heterozygosity of $-\alpha^{3.7}$ and $\alpha^{0}$ mutations leading to HbH disease, $\alpha$-triplication might exacerbate the proportional imbalance of $\alpha$ and $\beta$ chains and produce more severe phenotypes of $\beta$-thalassemia when $\alpha$-triplication is coinherited with $H B B$ variants $(12,22)$. In the case of HK $\alpha \alpha / \alpha \alpha$, it would be passed to the offspring as the $\alpha \alpha$ allele or HK $\alpha \alpha$ allele. Genetic modification of the HK $\alpha \alpha$ allele to other thalassemia subtypes was not obvious. In this study, MLPA analysis showed no net copy number change in the 4.2 region for the $H K \alpha \alpha /-\alpha^{4.2}$ genotype due to a $-\alpha^{4.2}$ deletion on one chromosome and a similarly sized $\alpha \alpha \alpha^{\text {anti } 4.2}$ duplication on the other chromosome, which might result in a false result (Figure 2C). Therefore, it is difficult to identify the HK $\alpha \alpha$ allele using the MLPA technique.

Two-round nested PCR is a classical method to detect the HK $\alpha \alpha$ allele (7). However, HK $\alpha \alpha / \alpha \alpha$, HK $\alpha \alpha / H K \alpha \alpha$, HK $\alpha \alpha / \alpha^{3.7}$, and HK $\alpha / \alpha \alpha \alpha^{\text {and }}{ }^{4.2}$ cannot be distinguished by two-round nested PCR. Chen et al. (21) suggested that the combination of gap-PCR, MLPA, and nested PCR could be used to detect HKa $\alpha$. MLPA and the two-round nested PCR method can verify each other and help differentiate HK $\alpha \alpha / \alpha \alpha$, HK $\alpha /$ /HK $\alpha \alpha$, HK $\alpha /-\alpha^{3.7}$, HK $\alpha \alpha /-\alpha^{4.2}$, HK $\alpha \alpha /$ HK $\alpha \alpha$, HK $\alpha \alpha / \alpha \alpha \alpha^{\text {and } 3.7}$, and HK $\alpha / \alpha \alpha \alpha^{\alpha n i}{ }^{\text {and }}$. However, this combination involves multiple sets of experiments, and
the process is cumbersome and time-consuming, making it difficult to achieve large-scale population screening in clinical practice.

Recently, TGS technology based on LMS has become an efficient, cost-effective, and accurate approach for comprehensive thalassemia carrier screening $(15,16)$. Using long-read single-molecule sequencing technology, TGS can accurately distinguish the highly homologous sequences of the HBA1 and HBA2 genes, and correctly discern the real genetic carrier status of complex structural variants and homologous recombination. For samples with compound heterozygotes, TGS can directly determine whether the genotypes are in cis or in trans without pedigree analysis. In this study, the subtypes of $\alpha$-thalassemia with the HK $\alpha \alpha$ allele were correctly detected by the TGS approach, including HK $\alpha \alpha / \alpha \alpha, H K \alpha \alpha /-\alpha^{3.7}, H K \alpha \alpha /-\alpha^{4.2}$, and $H K \alpha \alpha /-{ }^{\text {SEA }}$. In addition, a recent study also showed that more complex $\alpha$-globin gene cluster variants, such as $\alpha \alpha^{\text {anti3.7 }} \alpha^{\text {anti3.7 }} \alpha^{17.2} / \alpha \alpha$ and $-{ }^{\text {SEA }} / \alpha^{\text {Westmead }} \alpha^{\text {anti3.7+Westmead }} \alpha$, were identified by TGS testing (23). Therefore, longread TGS can greatly benefit resolving complex structural rearrangements and help improve the accuracy of genetic testing.

The HKad allele was confirmed by Sanger sequencing in our previous research (10). As described by our research group (10), the HKa allele sequence is divided into 3 regions: $-\alpha^{3.7}, \alpha \alpha \alpha^{\text {anti } 4.2}$, and a special region about 802 base pairs long. Interestingly, in the special 802 base pairs region, the upstream area is identical to the sequence of the $\alpha$-globin gene ranging from 171,116 to 171,235 , the downstream area is the same as that on the $\alpha$-globin gene and ranges from 171,223 to 171,882 , but the part that crosses them is the undetected sequence (NCBI Reference Sequence: Ng_0000016.10), which might be caused by the shortcomings of short reads. The PacBio long-read sequencing approach can overcome the limitations (14). In this study, the contiguous sequence of the HKa allele was detected using long reads of TGS technology. Moreover, we discovered that the sequence not detected in the previous study contained 17 T , which shared the same sequence with the $\alpha$-globin gene ranging from 171,219-171,235 (hg38). The sequence was lost in the splicing, so that it could not be detected by Sanger sequencing. By using long-read contiguous sequences, TGS technology greatly makes up for the limitation of short-read sequencing and provides full-length coverage of thalassemia alleles, including $H B A$ and $H B B$ genes. Surprisingly, 2 rare variants in $H B B[-50$ $(\mathrm{G}>\mathrm{A})$ and $-198 \mathrm{~A}>\mathrm{G}]$ were discovered when HKad samples
were subjected to the TGS assay. The mutation of $-50(\mathrm{G}>\mathrm{A})$ (HBB: c.-100G>A) was first reported by Li et al. in 2009 (24). Consistent with previous studies $(25,26)$, our result suggested that individuals with the $-50(\mathrm{G}>\mathrm{A})$ heterozygous variant had a normal hematological phenotype. Unexpectedly, our study showed that an individual with the -198 (A>G) (HBB: c. $-248 \mathrm{~A}>\mathrm{G})$ mutation exhibited microcytic hypochromic anemia, which was inconsistent with a previously reported result that the $-198(\mathrm{~A}>\mathrm{G})$ heterozygous variant has a normal hematological phenotype with decreased HbA 2 level (26). The reason was that the individual in our study had concomitant iron deficiency anemia with a serum ferritin of $9.73 \mathrm{ng} / \mathrm{mL}$. In short, longread TGS technology can identify both common and rare mutations in the $H B A$ and $H B B$ genes, thus improving the detection rate of rare thalassemia.

With sequencing of long reads, the biggest advantage of TGS is to directly identify the junction site of complex structural variants like HK $\alpha \alpha, \alpha$-globin gene triplications and even quadruplications. The accuracy of PacBio sequencing was guaranteed by two levels. First, the PacBio platform utilized a hairpin library structure which enables it to sequence the same insert (subread) for multiple passes to generate high fidelity CCS reads. Second, a minimum $60 \times$ coverage depth of $\alpha$-globin and $\beta$-globin genes was sequenced, which further proofed any sequencing errors in CCS reads. To reduce the cost per test, hundreds of barcoded samples need to be pooled together for sequencing in one flowcell, which might hinder the clinical application of TGS in small centers with limited number of samples. Pooling samples with different TGS-based tests like congenital adrenal hyperplasia, spinal muscular atrophy and fragile- X syndrome could be a solution. In addition, TGS cannot detect all the deletional thalassemia, so some difficult cases require the combination of clinical phenotype and multiple detection techniques to make a correct diagnosis.

Besides the methods mentioned above, researchers have reported that qPCR system and multicolor melting curve analysis can be used to detect the HKa $\alpha$ thalassemia $(12,13)$. However, they cannot directly determine whether the genotype is in cis or in trans, and further experiments are needed to verify. Next-generation sequencing (NGS) is an effective means of detecting rare thalassemia, but it is difficult to detect HK $\alpha \alpha$ due to the limitation of short-read length.

In conclusion, long-read TGS technology has significant advantages in detecting the HK $\alpha \alpha$ allele, and can accurately
distinguish various subtypes of HK $\alpha \alpha$ thalassemia, thus achieving accurate detection. The TGS method can help to comprehensively improve the detection level of thalassemia mutant genes in the population, and will be beneficial for clinical geneticists in carrying out genetic counseling for patients and making correct prenatal diagnoses.

## Acknowledgments

We thank Aiping Mao, Jiaqi Li, and Tiantian Xie from Berry Genomics Corporation for their assistance with TGS technology.
