Background: Cardiopulmonary exercise testing (CPET) has been found high sensitivity and specificity in cardiac ischemia. However, the role of CPET in coronary artery disease (CAD) is unclear. This study was to explore the diagnostic value of CPET indicators in CAD.

Methods: A total of 138 symptomatic patients with suspected CAD who underwent a CPET were included in this cross-sectional study. CPET indicators of all individuals were collected. $\Delta VO_2/HR_{(Peak-AT)}$ defined as the difference between the value of the oxygen consumption/heart rate (VO_2/HR) at anaerobic threshold and peak exercise. The synergy between percutaneous coronary intervention with taxus and cardiac surgery (SYNTAX) score of all the CAD patients was calculated based on the complexity of the coronary lesions. The diagnostic performance of the CPET indicators was assessed by the area under the curve (AUC), sensitivity, and specificity.

Results: No significant differences in the CPET indicators were observed among the patients with or without CAD. The high SYNTAX score (≥ 22) group showed a significant reduction in the $\Delta VO_2/HR_{(Peak-AT)}$ compared to the low SYNTAX score (< 22) group ($P=0.004$). The AUC of the $\Delta VO_2/HR_{(Peak-AT)}$ was 0.804 ($P=0.005$), with the sensitivity of 95.7% and the specificity of 62.5%. The other CPET indicators did not differ significantly between the 2 groups. Oxygen pulse variation after the anaerobic threshold (AT) is superior to other CPET-derived variables in detecting intermediate to severe stenosis of the coronary artery in CAD patients.

Conclusions: The $\Delta VO_2/HR_{(Peak-AT)}$ is a quantitative indicator of the variation of the oxygen pulse response after the AT during incremental exercise. However, due to sample limitations, our results need to be interpreted with caution.

Introduction

Coronary artery disease (CAD) is one of the leading causes of death in both developed and developing countries (1). The early diagnosis of CAD is essential for the proper management of patients. Coronary angiography is a commonly used diagnostic method in clinical practice.

However, it has some disadvantages, such as invasiveness, high examination cost, high requirements for physicians, advanced hospital equipment, and inapplicability to primary hospitals. Cardiopulmonary exercise testing (CPET), which combines an exercise stress test with ventilatory gas exchange measurements, has gradually been proven to

be related to cardiac dysfunction, and provides a unique approach to assessing exercise-induced myocardial ischemia. Research has shown that the analysis of CPET indicators has better sensitivity, specificity, and negative and positive predictive values for cardiac ischemia than the analysis of electrocardiography changes only (2,3).

Oxygen pulse, a CPET indicator, is the ratio of oxygen consumption (VO_2) to heart rate (HR) (VO_2/HR) and reflects increments in stroke volume and oxygen extraction. Currently, oxygen pulse is considered one of the most relevant variables of myocardial ischemia. In theory, the development of myocardial ischemia during exercise may decrease heart stroke volume, and may result in changes in oxygen pulse. Over the past 2 decades, most studies have evaluated the diagnostic performance of oxygen pulse using myocardial ischemia detected by myocardial perfusion scan as the diagnostic standard (2,4,5). However, to date, there has been little discussion of the value of oxygen pulse compared to coronary artery anatomy data, and different studies have reported different results. Chaudhry *et al.* (6) observed an incremental linear decline in peak oxygen pulse in men with the progression of atherosclerotic-burden, but less progression in women. Conversely, Mazaheri *et al.* (7) compared the CPET indicators in patients with a mean diameter reduction $>70\%$ in at least 1 coronary artery to patients without CAD and found no significant differences in the $\Delta VO_2/\Delta WR$, peak VO_2/HR , and the flattening duration of the oxygen pulse curve. This is likely due to the

unclear classification of the anatomical severity of coronary stenosis defined by coronary arteriography. To the best of our knowledge, the impact of CPET indicators in CAD and different severities of coronary artery stenosis is unclear.

In the present study, we investigated the diagnostic value of CPET indicators in CAD, and compare the oxygen pulse response to incremental exercise in patients with different severities of coronary artery stenosis. We present the following article in accordance with the STARD reporting checklist (available at <https://atm.amegroups.com/article/view/10.21037/atm-22-5279/rc>).

Methods

Patients selection

In this cross-sectional study, we assessed 138 patients with symptoms suggestive of CAD, who had been referred to Shanghai East Hospital (Tongji University School of Medicine) from July 2020 to July 2021. All the patients underwent both a coronary angiography and CPET in the diagnostic process. The 24 patients diagnosed with CAD also underwent an intravenous ultrasound (IVUS) test. The inclusion criteria were any symptoms suggestive of CAD, including chest pain, dyspnea, palpitations, and syncope with or without abnormal electrocardiography findings. The exclusion criteria were all contraindications of CPET and a history of CAD, heart failure, the presence of other cardiac diseases (e.g., valvular heart disease or cardiomyopathies), pulmonary disease, arrhythmias, and anemia. The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The study was approved by the institutional ethics board of Shanghai East Hospital (No. 2022_286). The requirement for informed consent was waived by the committee due to the retrospective nature of the study.

CPET

After a familiarization test, a symptom-limited, physician-supervised CPET was performed on an electromagnetically-braked cycle ergometer with a breath-by-breath analysis of ventilation and exhaled gas. All the tests were performed in accordance with the guidelines for cardiopulmonary exercise testing (CPX) of the American Heart Association and the American College of Sports Medicine (8,9). Patients were instructed not to eat for at least 2 h before the test, and not to drink tea, coffee, or cola drinks during that time. Before each test, the equipment was calibrated in a standard fashion

Highlight box

Key findings

- This study found that the difference between the value of the oxygen consumption/heart rate at anaerobic threshold and peak exercise [$\Delta VO_2/HR_{(Peak-AT)}$] achieved an area under the curve of 0.804 in the diagnosis of coronary artery disease, with the sensitivity of 95.7% and the specificity of 62.5%.

What is known and what is new?

- Cardiopulmonary exercise testing has gradually been proven to be related to cardiac dysfunction, which provides an assessment approach to myocardial ischemia.
- The impact of cardiopulmonary exercise testing indicators in coronary artery disease and different severities of coronary artery stenosis is unclear.

What is the implication, and what should change now?

- $\Delta VO_2/HR_{(Peak-AT)}$ may be considered for clinical application as a diagnostic factor of coronary artery disease to help clinicians implement early intervention and treatments.

according to the manufacturer's instructions. All the patients had a 3-min baseline period and a 3-min warm-up period (warm-up, 0 W, 60 rpm), followed by the incremental exercise test, and a 5-min cool-down after exercise. The incremental exercise test used a customized linear-ramp protocol designed to elicit fatigue within 8–12 min of exercise. Blood pressure was measured and recorded automatically every 2 min. A 12-channel electrocardiogram (ECG) was used, and oxygen saturation was monitored throughout the duration of the test. The standard criteria for test termination included dyspnea, moderately severe angina, abnormal ST depression (>2 mm) in at least 2 adjacent leads, severe arrhythmia, a sustained drop in systolic blood pressure, and marked hypertension (>250/130 mmHg) (9). In the absence of each of the above-mentioned criteria, the patients were encouraged to exert their maximal effort [respiratory exchange ratio (RER) target >1.0].

The VO_2 , carbon dioxide production (VCO_2), and minute ventilation (VE) were continuously measured on a breath-by-breath basis. The anaerobic threshold (AT) was determined using the V-slope method (10). Peak oxygen uptake (peakVO_2) was the average oxygen uptake during the last 15 s of the exercise. Predicted peak VO_2 was the percentage of VO_2 peak predicted by the anthropometric data. $\Delta\text{VO}_2/\Delta\text{WR}$ was automatically calculated by linear regression using the following formulae:

$$\Delta\text{VO}_2/\Delta\text{WR} = \text{peak VO}_2 - \text{rest VO}_2 / (T - 0.75) \times S \quad [1]$$

where T is the time of incremental exercise, and S is the slope of work rate increment in watts per minute (11). VE/VCO_2 was the slope of ventilation versus CO_2 output. The relationship between oxygen uptake and ventilation was expressed by the oxygen uptake efficiency slope (OUES) and was calculated using the following equation (8):

$$\text{VO}_2 = \text{OUES} \times \log \text{VE} + b \quad [2]$$

The oxygen pulse (VO_2/HR) was calculated by dividing the VO_2 by the heart rate throughout exercise, and peak VO_2/HR was the percentage of the predicted VO_2/HR . We also introduced new CPET indicators, including the $\Delta\text{VO}_2/\text{HR}_{(\text{Peak-AT})}$, which was defined as the difference between the value of the VO_2/HR at the AT and peak exercise.

Coronary angiography, IVUS, and taxus and cardiac surgery (SYNTAX) score

Coronary angiography and IVUS was performed through the radial artery using standard techniques within 2 days

of CPET. Angiograms were obtained from multiple projections of coronary arteries and analyzed by 2 experienced cardiologists. Each segment was numerically evaluated according to the percentage reduction in the lumen diameter based on the nearest proximal intact coronary artery segment. CAD was diagnosed if stenosis was >30% in the left main artery and/or >50% in any other coronary arteries. The lesion site selected for the IVUS analysis was the image slice with the minimal lumen area (MLA) and area stenosis (AS), which were measured following the guidelines for IVUS measurements of the American College of Cardiology (12). Angiograms were also scored according to the SYNTAX score algorithm (13) by the 2 experienced cardiologists.

Statistical analysis

The statistical analysis was performed using the IBM SPSS Statistics 26.0 software package. The results for the continuous variables are expressed as the mean \pm standard deviation (SD), and the categorical data are expressed as percentages. An analysis of the normality of the continuous variables was performed using the Kolmogorov-Smirnov test. The student's *t*-test was used to compare continuous variables between groups. The categorical data were analyzed using the chi-square test or Fisher's exact test. The receiver operating characteristic (ROC) curve was used to assess the optimal $\Delta\text{VO}_2/\text{HR}_{(\text{Peak-AT})}$ threshold value, which maximized the sensitivity and specificity averages for predicting moderate and severe stenosis of the coronary artery. The area under the curve (AUC) >0.8 was considered to have a good diagnostic performance. Two-sided P value <0.05 was considered statistically significant.

Results

Patients

In total, 138 patients were included in this study. No myocardial infarctions or deaths resulted from the tests. The patients were grouped according to the results of the coronary angiography. Group 1 comprised 60 patients with <30% stenosis in the left main artery and <50% stenosis in any other coronary arteries. Group 2 comprised 78 patients with significant coronary lesions. *Table 1* sets out the patients' characteristics by group. More patients were taking antiplatelet medication and nitrates in Group 2 than Group 1, as the Group 2 patients had more significant

stenosis. There were no significant differences between the 2 groups in terms of age, gender, body mass index (BMI), left ventricular ejection fraction (LVEF) at rest, and conventional coronary risk factors.

The CPET indicators of patients with and without CAD are set out in *Table 2*. The peak RER, peak workload, and predicted peak workload were similar in the 2 groups. Additionally, the peak HR, heart rate reserve (HRR), 1st minute of HR recovery, and peak systolic blood pressure did not differ significantly between the patients with and without CAD. The patients with CAD had a lower VO₂ at peak exercise; however, it did not differ significantly to that of the patients without CAD (18.65 \pm 3.92 *vs.* 19.26 \pm 3.57 mL/kg/min, P=0.344). Patients' ventilation performance during CPET was also similar between the 2 groups, which was characterized by variables compatible with peak VE, predicted peak VE, OUES, and VE/VCO₂. As for the relevant variables for myocardial ischemia, the 2 groups showed a continuous and similar increase in VO₂/HR (10.14 \pm 2.38 *vs.* 10.78 \pm 3.08 mL/beat, P=0.171) and

Δ VO₂/ Δ WR (10.09 \pm 1.14 *vs.* 10.05 \pm 1.29 mL/watt/min, P=0.828) during exercise. The Δ VO₂/HR_(Peak-AT) mean value in the CAD group was 1.10 \pm 0.95 mL per beat, while that in the non-CAD group was 1.26 \pm 1.14 mL per beat (P=0.394).

Table 3 shows the CPET indicators stratified by the SYNTAX scores based on the coronary angiography results of the patients with CAD. The high SYNTAX score group comprised 8 patients with a SYNTAX score >22, and no characteristic differences were found between the 2 groups. Similarly, no differences were observed in terms of the peak RER, peak workload, predicted peak workload, peak HR, HRR, 1st min of HR recovery results, peak systolic blood pressure, and ventilation variables. Additionally, the peak VO₂/HR (10.89 \pm 2.88 *vs.* 10.06 \pm 2.33 mL/beat, P=0.352) and Δ VO₂/ Δ WR (9.75 \pm 0.92 *vs.* 10.13 \pm 1.16 mL/watt/min, P=0.369) of the CAD patients with high SYNTAX scores did not differ significantly to those of the CAD patients with low SYNTAX scores. However, the Δ VO₂/HR_(Peak-AT) was significantly lower in the high SYNTAX score group than that in the low SYNTAX score group (0.20 \pm 0.84 *vs.*

Data are presented as mean ± SD. CAD, coronary artery disease; RER, respiratory exchange ratio; HR, heart rate; HRR, heart rate reserve; SBP, systolic blood pressure; OUES, oxygen uptake efficiency slope; SBP, systolic blood pressure; VE, ventilation; VCO₂, carbon dioxide production; VO₂, oxygen consumption; WR, work rate; AT, anaerobic threshold.

1.21±0.91 mL/beat, P=0.004). A ROC curve was generated to determine the best cut-off value for the ΔVO₂/HR_(Peak-AT). The AUC was 0.804 [95% confidence interval (CI): 0.617–0.99, P=0.005] (see *Figure 1*). The value of –0.0074 mL per beat corresponded to the maximum joint sensitivity and specificity of the ROC curve (95.7% sensitivity and 62.5% specificity), which was defined as the cut-off value.

Among the 24 CAD patients undergoing IVUS, 13 had a percentage AS <65%, with a mean minimal lumen area-IVUS (MLA-IVUS) of 4.52±1.00 mm², while the other 11 had a percentage AS >65% and had a significantly lower MAL-IVUS of 3.42±0.84 mm² (P=0.009). Additionally, the group with a percentage AS >65% had a slower increase of O₂ pulse and a significantly lower ΔVO₂/HR_(Peak-AT) (0.71±0.87 vs. 1.53±0.89 mL per beat, P=0.034). The other CPET indicators investigated, including the peak VO₂/HR and ΔVO₂/ΔWR, were similar between the 2 groups (*Table 4*).

Discussion

CPET, which is an important non-invasive tool, provides objective and reproducible variables that may be used for the diagnostic and prognostic evaluation of cardiovascular disease. However, in recent years, relatively few studies have researched CPET. Thus, CPET is not usually employed to its full clinical potential. Our study evaluated the diagnostic application of CPET in CAD assessment, using the oxygen pulse related variable as an indicator of exercise-induced ischemia, and compared it to objective evidence of CAD based on coronary angiography.

Oxygen pulse is a measure of oxygen consumed per heartbeat obtained at CPET, which provides an estimate of LV stroke volume changes during exercise, assuming that the C_(a-v)O₂ is maximal, and no anemia is present (14). During the exercise-induced myocardial ischemic cascade, metabolic abnormalities, diastolic dysfunction, systolic

dysfunction, and ECG changes occur in a sequential manner (15). This indicates that the change of oxygen pulse occurs early in the process of the myocardial ischemia and is manifested by a decrease in the value of oxygen pulse and the oxygen pulse trajectory prematurely flattening or declining (16). However, in this study we found no significant difference in peak VO_2/HR between patients with or without CAD. Our results supported Mazaheri's findings (7). Mazaheri also used the coronary angiography as the gold standard for diagnosing CAD and reported that while patients with CAD had a lower VO_2/HR at peak exercise, it did not differ significantly to that of patients without CAD ($P=0.61$). Conversely, Chaudhr (6) demonstrated an incremental linear decline in the peak VO_2/HR value with progression of atherosclerotic-burden.

Several studies have evaluated the diagnostic performance of the oxygen pulse using myocardial ischemia detected by myocardial perfusion scan as the diagnostic standard. Belardinelli (2) showed that ischemia patients diagnosed

by Gated- single photon emission computed tomography (SPECT) had a significantly lower peak VO₂/HR, while Pinkstaff (4) and Chen (5) found that the peak VO₂/HR could not be used to identify patients with myocardial ischemia. This discrepancy could be attributed to the different severities of ischemia in these studies, as oxygen pulse response during incremental exercise might only present with extensive myocardial ischemia (17,18). In the current study, we found no significant differences in the peak VO₂/HR between the low and high SYNTAX score groups, as similar as between the IVUS-AS <65% and ≥65% groups. This may be because the patients who were referred to our center for CPET with symptoms of suspected ischemic CAD were usually in a good physical condition.

In Belardinelli's study, 86% of CAD patients had at least 2 coronary arteries with >50% stenosis and 91% had positive myocardial scintigraphy (2). Conversely, in

our study only 22 (28%) CAD patients had more than 1 coronary artery with >50% stenosis. The severity of coronary artery stenosis in our patients may be insufficient to induce extensive myocardial ischemia to achieve a positive result of an oxygen pulse response during exercise, indicating that a decrease in the peak oxygen pulse has low sensitivity and specificity for the diagnosis of patients with mild to moderate coronary artery stenosis, and has no positive predictive effect in assessing the severity of coronary artery stenosis.

In 2003, duration of oxygen pulse flattening was reported to be an independent predictor of myocardial ischemia detected by a positive myocardial scintigraphy (2). Since then, the focus has begun to shift to the trajectory of the oxygen pulse curve. However, the results remain controversial. Chaudhry (6) demonstrated that the oxygen pulse trajectory provides valuable information that can

be used to evaluate patients with CAD. Conversely, De Lorenzo (19,20) classified the oxygen pulse curves into 4 patterns and found that the oxygen pulse curve pattern had low diagnostic performance in the diagnosis of CAD, and the abnormal curve pattern was not associated with myocardial ischemia defined by scintigraphy. Unfortunately, the process of identifying the oxygen pulse curve pattern may be highly subjective. Thus, we introduced the variable of $\Delta VO_2/HR_{(Peak-AT)}$, which was defined as the difference between the value of VO_2/HR at the AT and peak exercise, to try to quantify the variation of the oxygen pulse curve pattern. The smaller the value, the less the oxygen pulse curve increase or the more the oxygen pulse curve decreases after the AT. We found no significant difference in the $\Delta VO_2/HR_{(Peak-AT)}$ between the CAD group and the non-CAD group. However, the patients with high SYNTAX scores showed a significant reduction in the $\Delta VO_2/HR_{(Peak-AT)}$ compared to the patients with low SYNTAX scores.

There was also a significant difference in the $\Delta VO_2/HR_{(Peak-AT)}$ between groups divided according to the IVUS-AS. The patients with a high SYNTAX score or IVUS-AS >65% generally had the more severe stenosis of the coronary artery, which means that they are likely to show more extensive myocardial ischemia during exercise. Thus, our results further support the idea that the variation in the oxygen pulse response to incremental exercise can detect extensive but not mild myocardial ischemia, and the value of $\Delta VO_2/HR_{(Peak-AT)}$, as a quantified variable of oxygen pulse curve development, has higher sensitivity in detecting myocardial ischemia than other CPET indicators.

It is somewhat surprising that no differences were found in the remaining variables of CPET, including peak VO_2 and $\Delta VO_2/\Delta WR$, which are also considered to be related to myocardial ischemia (2,21,22). This finding might also be attributed to the differences in the patient populations between studies. In our study, 72% of the CAD patients had >50% stenosis in only 1 coronary artery, and 10.3% of the CAD patients with a high SYNTAX score (≥ 22) had a moderate to severe obstructive coronary artery. Thus, our results are likely to be related to the mild myocardial ischemia of these patients. This suggests that, as with the VO_2/HR , the variation in the $\Delta VO_2/\Delta WR$ response to exercise and peak VO_2 are not sensitive to mild and moderate myocardial ischemia.

One limitation of the present study was the lack of myocardial perfusion scintigraphy data and LV function during exercise, which could help to identify of the extent of the myocardial ischemia. Additionally, the patients in

the non-CAD group also had symptoms, and we could not exclude the possibility of micro-vascular ischemia, as the coronary arteriography and IVUS could only assess the proximal vessels of the coronary artery. It has previously been observed that micro-vascular ischemia is becoming increasingly recognized in symptomatic patients, especially in women with angiographically normal coronary arteries (23). Thus, having age- and sex-matched asymptomatic, relatively sedentary individuals without cardiovascular risk factors would have made for a more ideal healthy cohort. However, it was not feasible in this clinical observational study. Another limitation of this study was the small sample size, especially that of patients with severe stenosis of coronary artery. This difference in the patient populations between the groups may have had an effect on our findings. Thus, continued investigations with a larger sample size are needed.

Conclusions

This study showed that the decrease in the peak oxygen pulse response to incremental exercise was not generally present in patients with mild to moderate myocardial ischemia. The variable of $\Delta VO_2/HR_{(Peak-AT)}$, which has been identified as a quantitative indicator for the variation of oxygen pulse response after the AT during incremental exercise, has been shown to have good predictive ability for identifying the stenosis of the coronary artery. Future research in this area should seek to quantifiably determine the value of CPET in diagnosing CAD and assessing the function of the coronary artery compared to other variables [e.g., fractional flow reserve (FFR) and quantitative flow ratio (QFR)] to guide interventional treatments.
