Background: Head and neck squamous cell carcinoma (HNSCC) patients with a high tumor grade, lymphovascular invasion (LVI), or perineural invasion (PNI) tend to demonstrate a poor prognosis in clinical series. Thus, the identification of histopathological features, including tumor grade, LVI, and PNI, before treatment could be used to stratify the prognosis of patients with HNSCC. This study aimed to assess whether quantitative parameters derived from pretreatment dual-energy computed tomography (DECT) can predict the histopathological features of patients with HNSCC.

Methods: In this study, 72 consecutive patients with pathologically confirmed HNSCC were enrolled and underwent dual-phase (noncontrast-enhanced phase and contrast-enhanced phase) DECT examinations. Normalized iodine concentration (NIC), the slope of the spectral Hounsfield unit curve (λ_{HU}), and normalized effective atomic number (NZ_{eff}) were calculated. The attenuation values on 40–140 keV noise-optimized virtual monoenergetic images [VMIs (+)] in the contrast-enhanced phase were recorded. The diagnostic performance of the quantitative parameters for predicting histopathological features, including tumor grade, LVI, and PNI, was assessed by receiver operating characteristic curves.

Results: The NIC, λ_{HU}, NZ_{eff}, and attenuation value on the VMIs (+) at 40 keV (A_{40}) in the grade III group, LVI-positive group, and PNI-positive group were significantly higher than those in the grade I and II groups, the LVI-negative group, and the PNI-negative group (all P values <0.05). A multivariate logistic regression model combining these 4 quantitative parameters improved the diagnostic performance of the model in predicting tumor grade, LVI, and PNI (areas under the curve: 0.969, 0.944, and 0.931, respectively).

Conclusions: Quantitative parameters derived from pretreatment DECT, including NIC, λ_{HU}, NZ_{eff}, and $A_{4,0}$ were found to be imaging markers for predicting the histopathological characteristics of HNSCC. Combining all these characteristics improved the predictive performance of the model.

Keywords: Dual-energy scanned projection; squamous cell carcinoma of head and neck; pathology

Introduction

Head and neck squamous cell carcinoma (HNSCC) is a malignancy developing from mucosal epithelium in the oral cavity, pharynx, larynx, and other sites. There are more than 500,000 new cases of HNSCC reported every year worldwide (1). HNSCC patients with high tumor grade, lymphovascular invasion (LVI), or perineural invasion (PNI) tend to demonstrate a poor prognosis in clinical series. Thus, the identification of histopathological features, including tumor grade, LVI, and PNI, before treatment could be used to stratify the prognosis of patients with HNSCC (2-7) and to identify patients who should receive more aggressive treatments (8).

Invasive biopsy is widely used to determine the histopathological features of HNSCC, but its application is limited due to complications, such as bleeding, and a lack of tumorous histopathological characteristics (9). Single-energy computed tomography (SDCT) shows the morphological features of HNSCC; however, as these morphological features are subjectively and qualitatively evaluated by radiologists, the results partially depend on the observers' experience (10-12). As SDCT fails to accurately predict the histopathological features of tumors, a noninvasive quantitative analysis of the histopathological features before treatment could be clinically meaningful in treatment planning and consequently improve patient prognosis.

Dual-energy computed tomography (DECT) is an advanced imaging technique that allows 2 series of CT images to be acquired at different energies (13). DECT can provide a series of quantitative parameters, including iodine concentration (IC), attenuation values at different energy levels, such as 40–140 keV, and effective atomic number (Zeff), to represent the essential characteristics of tumors (14-18). These quantitative parameters have been shown to be beneficial in the differential diagnosis, staging, and prognostic prediction of HNSCC (19-22). However, very little is currently known about the value of quantitative parameters derived from DECT in the pretreatment prediction of histopathological features in patients with HNSCC. Thus, this study sought to determine whether quantitative parameters derived from pretreatment DECT could predict these histopathological features in patients with HNSCC.

We present the following article in accordance with the STARD reporting checklist (available at https://dx.doi.org/10.21037/qims-21-650).

Methods

Data collection occurred after the surgical pathological results were collected. The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). This retrospective study was approved by the Ethics Committee of Chongqing University Cancer Hospital, and written informed consent was waived.

From December 2018 to July 2020, 89 consecutive patients with findings highly suspicious of HNSCC underwent DECT. To be eligible to for study enrollment, patients had to meet the following inclusion criteria: (I) histopathologically confirmed HNSCC, (II) no history of allergy to iodine contrast agents, and (III) no history of antitumor therapy before DECT examination. Patients were excluded from this study if they (I) had severe image artifacts, (II) incomplete clinical and histopathological data, or (III) a primary tumor with a maximum diameter <10 mm on polyenergetic images (PEI).

DECT image acquisitions

All patients underwent dual-phase (nonenhanced phase and contrast agent-enhanced phase) DECT scans with a dual-source CT scanner (SOMATOM Drive, Siemens Healthineers, Forchheim, Germany) and 100 kVp and Sn140 kVp tubes. All the scans were performed with an automatic exposure control (CARE Dose 4D, Siemens Healthineers) under the following settings: a reference tube current time product of 104 mAs for the Sn140-kVp tube and 134 mAs for the 100-kVp tube, a collimation of 32 mm × 0.6 mm, a rotation time of 0.5 s, a pitch of 0.7, a section thickness of 1.5 mm, and a section increment of 1.2 mm.

Patients were then injected with nonionic contrast medium (ioversol, 320 mg/mL iodine; Jiangsu Hengrui Medicine, Jiangsu, China) via antecubital venous access. The iodinated contrast medium was injected at a dose of 1.5 mL/kg and a rate of 2.5 mL/s. A bolus-tracking technique was used to perform the enhanced phase with a delay of 30 s after the arcus aorta at the threshold of 100 HU.

DECT image reconstruction

All the postprocessing of the DECT images was performed at a dedicated workstation (syngo.via VB20A, Dual Energy, Siemens Healthineers). PEIs in both the unenhanced and enhanced phases were reconstructed with a mix factor of 0.4 (M_0.4; 40% of the low kV and 60% of the high-kV

spectrum). Virtual monoenergetic images (VMIs) at 40 and 110 keV were reconstructed using contrast-enhanced phase images. The parameters of the reconstructed images were as follows: transverse sections; thickness, 1.5 mm; increment, 1.2 mm; and soft-tissue kernel, J30f.

Qualitative DECT imaging analysis

Two radiologists with 7 and 15 years of experience in head and neck CT imaging interpretation independently assessed the subjective and objective quality of the images using the same approach as that adopted in our previous study (see the Supplementary Materials) (23). The radiologists evaluated the morphological features on the VMIs with optimal image quality. The radiologists were blinded to patient information and the histopathological results. The morphological features included heterogeneous density (presence or absence), ill-defined margins (presence or absence), the infiltration of adjacent structures, such as muscle or cartilage or bone (presence or absence), and the degree of enhancement (high, intermediate, or low). The degree of enhancement was defined as per our previous study (23).

Analysis of quantitative DECT parameters

All the quantitative parameters were independently measured by the above mentioned 2 radiologists, who were blinded to patient information and the histopathological results. To assess intraobserver variability, the first radiologist evaluated the images twice with an interval of 2 weeks. The regions of interest (ROIs) were placed on a single slice in the largest tumoral area on the axial images, and areas of necrosis and artifact were avoided. The average values of the quantitative parameters (which were measured 3 times, twice by observer 1 and once by observer 2) were used for the subsequent analysis.

The normalized IC (NIC), slope of the spectral Hounsfield unit curve (λ_{HU}), and normalized Zeff (NZ_{eff}) values were calculated using the following formulas: NIC = IC value of primary lesion/IC value of common carotid artery; λ_{HU} = (attenuation value of primary lesion in 40 keV – attenuation value of primary lesion in 110 keV)/70; and NZ_{eff} = Zeff value of primary lesion/Zeff value of common carotid artery. IC values were measured in the "VNC" mode at the syngo.via workstation using the enhanced images. The attenuation values of the primary lesions at 40–140 keV VMIs (A_{40}, A_{50}, A_{60}, A_{70}, A_{80}, A_{90}, A_{100}, A_{110}, A_{120}, A_{130}, and

A_{140}) were measured. The Zeff values were measured in the "Rho/Zeff" mode at the syngo.via workstation using the nonenhanced phase images. The attenuation values in both the unenhanced phase (A_n) and the enhanced phase (A_e) PEIs were obtained. Their difference value (ΔA) was calculated as follows: $\Delta A = A_e – A_n$.

Histopathological analysis

All the surgically resected HNSCC specimens were used for the pathological evaluations. A pathologist with 20 years of experience in head and neck pathology who knew the clinical information of patients but was blinded to the DECT data analyzed these samples using hematoxylin and eosin staining and an immunohistochemistry panel. The pathologically differentiated grades of HNSCC were divided into the following 3 groups according to the eighth edition of American Joint Committee on Cancer Stage (AJCC): well differentiated (grade I), moderately differentiated (grade II), and poorly differentiated (grade III). LVI status and PNI status were classified as either positive or negative. The histopathological results were used as reference standards according to the long-time experience.

Statistical analysis

Statistical analyses were performed using SPSS statistics version 25.0 (IBM Corporation, Armonk, NY, USA). All the variabilities of the quantitative parameters derived from the DECT were exploratory. Intraclass correlation coefficients (ICCs) and Bland-Altman plots were used to assess intra- and interobserver agreement in relation to the quantitative parameters. The normality of the quantitative data distribution was evaluated using the Kolmogorov-Smirnov test. An independent sample t test and a 1-way ANOVA with a Bonferroni post hoc test were used to assess the differences between the quantitative data with normal distributions. The Mann-Whitney U test and Kruskal-Wallis with a Bonferroni post hoc test were used to assess the differences between the quantitative data without normal distributions. The performances of the observers in distinguishing the histopathological features were evaluated by a receiver operating characteristic (ROC) curve analysis. The Youden index was used to determine the optimal threshold. The Delong test was used to compare the differences of the areas under the curves (AUCs). The independent predictive parameters for the histopathologic

features were determined by a binary logistic regression analysis. A 2-sided P value <0.05 indicated a statistically significant difference. We performed an *a priori* power calculation using R 3.6.2 software with the "pwr" package (The R Foundation for Statistical Computing). The minimum sample size required to obtain 90% power in differentiating tumor grade, LVI, and PNI was 20 cases per group.

Results

Patients

Of the 89 patients enrolled in this study, 17 patients were excluded (5 due to poor quality images, 8 due to incomplete clinical or histopathological data, and 4 with maximum axial diameters of the primary tumor <10 mm). Ultimately, 72 patients were enrolled in the study (40 males and 32 females; median age 60 years, interquartile range, 53–70 years; see Figure S1). The clinical characteristics of the enrolled patients are shown in *Table 1*. No adverse events were observed in this study.

Intra-and interobserver agreement

The NIC, λ_{HU}, NZ_{eff}, A_{40}, A_{50}, A_{60}, A_{70}, A_{80}, A_{90}, A_{100}, A_{110}, A_{120}, A_{130}, A_{140}, An, Ae, and ΔA showed good intra- and interobserver agreement (ICC: 0.886–0.997; see *Table 2*). The Bland-Altman plots of the NIC, λ_{HU}, NZ_{eff}, and A_{40} are shown in *Figures 1,2*.

Comparison of DECT morphological features in relation to different histopathological features

The VMIs at 40 keV had the highest overall image quality and demarcation of lesion margins scores, signal-to-noise ratio (SNR), and contrast-to-noise ratio (CNR) (see Tables S1,S2 and Figure S2). Thus, a qualitative DECT analysis of HNSCC was performed on the 40 keV VMIs. None of the morphological features could be used to distinguish the grade III group from the grade I and II groups, the LVI-positive group from the LVI-negative group, and the PNI-positive group from the PNI-negative group (see Table S3).

Table 2 Intra- and interobserver reproducibility of measurements for quantitative dual-energy CT parameters

Parameters	Intraobserver agreement (95% CI)	Interobserver agreement (95% CI)
NIC	0.924 (0.881–0.954)	0.905 (0.853–0.940)

A_{100} (HU)	0.910 (0.843–0.936)	0.900 (0.829–0.927)
A_{110} (HU)	0.913 (0.855–0.939)	0.904 (0.839–0.933)
A_{120} (HU)	0.896 (0.815–0.933)	0.889 (0.805–0.931)
A_{130} (HU)	0.892 (0.805–0.930)	0.890 (0.800–0.928)
A_{140} (HU)	0.893 (0.811–0.935)	0.889 (0.801–0.925)
A_n (HU)	0.950 (0.921–0.968)	0.909 (0.854–0.943)
A_e (HU)	0.899 (0.839–0.937)	0.890 (0.823–0.931)
ΔA (HU)	0.890 (0.821–0.928)	0.886 (0.801–0.914)

CT, computed tomography; CI, confidence interval; NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZ_{eff}, normalized effective atomic number; VMI (+), noise-optimized virtual monoenergetic images; $A_{40–140}$, attenuation value in enhanced VMIs (+) at 40–140 keV; A_n, attenuation value in nonenhanced polyenergetic images; A_e, attenuation value in enhanced polyenergetic images.

Comparison of DECT parameters in relation to different histopathologic features

The DECT quantitative parameters and conventional attenuation values are summarized in *Tables 3,4* and *Figures 3,4*. The NIC, λ_{HU}, NZ_{eff}, and A_{40} values derived from the DECT in the grade III group were significantly higher than those in the grade I and II groups (all P values <0.05). The NIC, λ_{HU}, NZ_{eff}, and A_{40} values in the LVI-positive group were higher than those in the LV-negative group, while the NIC, λ_{HU}, NZ_{eff}, and A_{40} values in the PNI--positive group were also higher than those in the PNI-negative group (all P values <0.05). However, A_{50}, A_{60}, A_{70}, A_{80}, A_{90}, A_{100}, A_{110}, A_{120}, A_{130}, A_{140}, A_n, A_e, and ΔA showed no significant differences between any 2 tumor grade groups, between the

LVI-positive group and the LVI-negative group, or between the PNI-positive group and the PNI-negative group.

Diagnostic performance of the DECT parameters in predicting histopathological features

The AUC values of NIC were higher than those of λ_{HU}, NZ_{eff}, and A_{40} in distinguishing the grade III group from the grade I and II groups, the LVI-positive group from the LVI-negative group, and the PNI-positive group from the PNI-negative group. In the multivariable binary logistic regression analysis, compared to any single parameter, a combination of these 4 quantitative parameters obtained the highest AUC values for predicting tumor grade, LVI, and PNI (all P values <0.05; see *Table 5* and *Figure 5* and Figure S3).

Discussion

Histopathological features, including tumor grade, LVI and PNI, are highly associated with the prognosis of patients with HNSCC (23,24). However, SDCT cannot be used to accurately assess these histopathologic features before biopsy (25,26). DECT is an emerging CT imaging technique that provides multiple quantitative parameters for characterizing the intrinsic characteristics of tumors in the head and neck (27,28). In our study, the quantitative parameters derived from pretreatment DECT successfully predicted tumor grade, LVI, and PNI in patients with HNSCC. Further, combining these quantitative parameters improved the predictive performance of the model.

The histological grade of HNSCC at pretreatment has long been considered to be important prognostic factor (29). Tumors with a high grade are characterized by more tumor angiogenesis and higher cellularity, which indicate a poor prognosis (2). In our study, we found that the NIC values of grade III HNSCC were higher than those of grades I and II HNSCC. These results are in line with research findings on colorectal cancer and lung adenocarcinoma (30,31). It may be that high-grade tumors with abundant tumor neovascularization result in increased tumor blood supply and increased iodine uptake (32). Additionally, immature neovascularization endothelial cells in high-grade tumors may result in more extravascular contrast media leakage (33). Consistent with the findings of a previous study (34), we found that the λ_{HU} values of grade III HNSCC were higher than those of grades I and II HNSCC. When the contrast is enhanced, λ_{HU} values might indicate the rate of attenuation changes in tumors, and higher λ_{HU} values may represent a

higher percentage of iodine contrast media in tumors (17). Consequently, high-grade tumors with abundant tumor blood supply and higher iodine uptake will result in higher λ_{HU} values (35). The NZ_{eff} reflects the atomic number of the composition in the tumor tissue: the denser the tumor tissue, the higher the effective atomic number (19). We found that the NZ_{eff} values of grade III HNSCC were higher than those of grades I and II HNSCC. It may be that high-grade HNSCC with abundant and densely packed tumor cells leads to an increase in NZ_{eff} values (36).

LVI has been defined as cancer cells in peritumoral lymphatic vessels or small nonmuscularized blood vessels or both (37). It is associated with biologically aggressive

diseases and the systemic dissemination of cancer cells (38). Previous studies have shown that pretreatment CT provides a noninvasive method for predicting LVI in gastric cancer and rectal cancer (26,39). A recent study showed that radiomic analyses based on pretreatment CT images could successfully predict LVI in patients with HNSCC (40). Based on the above studies, we used DECT to predict LVI in HNSCC and found that the NIC, λ_{HU}, and NZ_{eff} values of the LVI-positive group were higher than those of the LVI-negative group. There could be a number of reasons for these results. First, vascular invasion in LVI-positive tumors increases the extravascular leakage of contrast agents and leads to higher NIC and λ_{HU} values. Second,

Data are presented as the mean ± standard deviation. Independent samples t-test. A P value <0.050 is statistically significant. CT, computed tomography; NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZ_{eff}, normalized effective atomic number; VMI (+), noise-optimized virtual monoenergetic images; $A_{40\text{-}140}$, attenuation value in enhanced VMIs (+) at 40–140 keV; A_{n}, attenuation value in nonenhanced polyenergetic images; A_{e}, attenuation value in enhanced polyenergetic images; $\Delta A = A_{e} - A_{n}$.

LVI demonstrates a positive correlation with tumor size and dissemination (41). Thus, tumor cells with relatively active proliferation in LVI-positive patients may increase the cell density of tumoral tissues, leading to an increase in Zeff values (4).

PNI is defined as the movement of cancer cells into the neural space, usually into small nerves (42). PNI has been shown to be associated with poor survival outcomes in patients with HNSCC and to indicate radical surgery and adjuvant radiochemotherapy (5). A previous study showed that heterogeneity features in primary tumors (as observed in pretreatment CT scans) can be used to predict PNI in patients with HNSCC (39). Another recent study showed that quantitative DECT could predict PNI in perihilar cholangiocarcinoma (43). On the basis of these studies, we applied quantitative parameters derived from DECT, which characterize the heterogeneity of tumor angiogenesis and cell proliferation, to predict PNI in patients with HNSCC. We found that the NIC values of the PNI-positive group were higher than those of the PNI-negative group. It may be that the increase of axon guidance molecules, including netrins, semaphorins, and ephrins, in PNI-positive patients promote the adhesion of tumor cells to peripheral nerves and tumor angiogenesis (44). An increase in tumor angiogenesis results in higher iodine uptake, which in turn increases NIC values. The NZ_{eff} values of the PNI-positive group were higher than those of the PNI-negative group. The tumor cells in the PNI-positive HNSCC have been shown to upregulate the genes that increase cell proliferation (45). Thus, increased cell proliferation may increase the density of tumoral tissue and result in higher NZ_{eff} values.
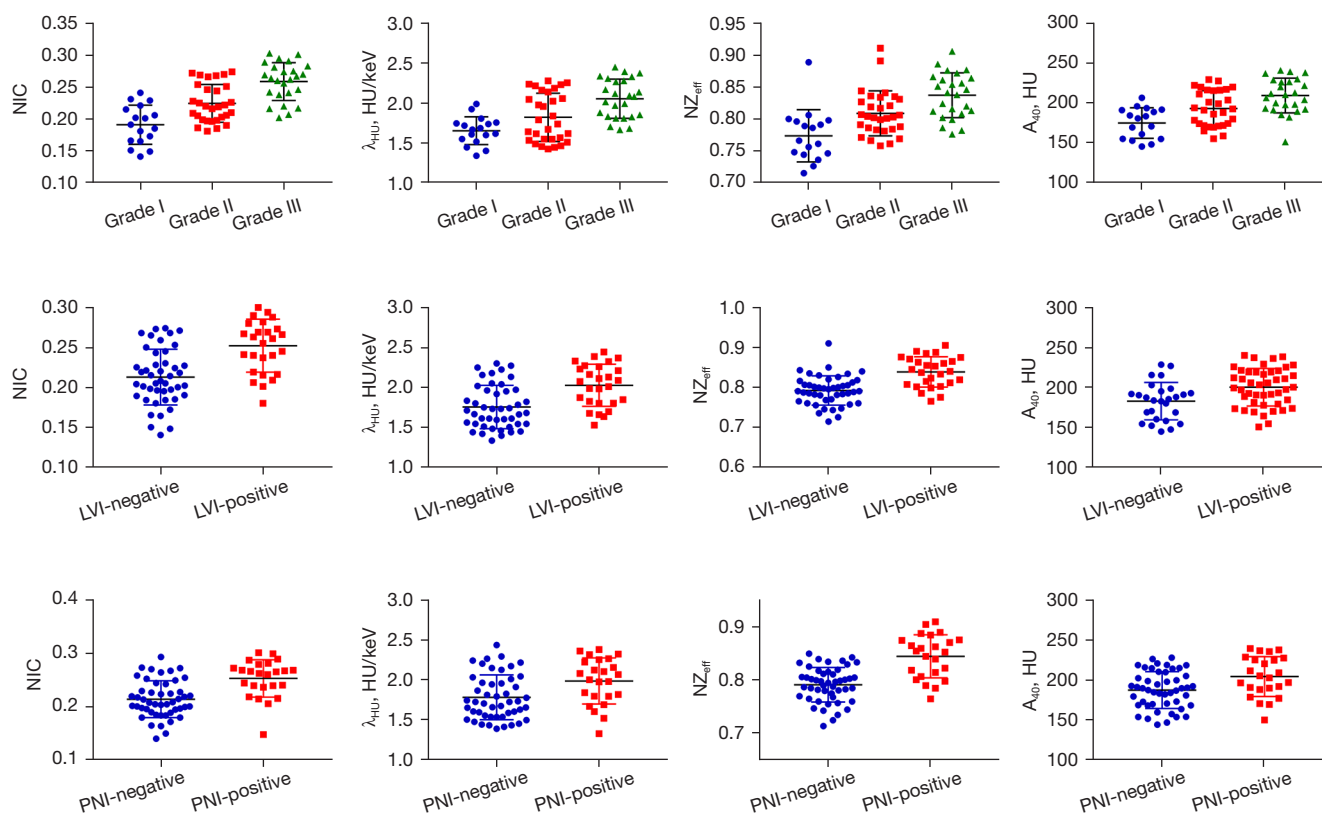

Figure 3 Quantitative parameters derived from dual-energy CT for different tumor grades, LVI, and PNI groups in patients with head and neck squamous cell carcinoma. The NIC, λ_{HU}, NZ_{eff}, and A_{40} values of the grade III group, LVI-positive group, and PNI-positive group were significantly higher than those of the grade I and II groups, LVI-negative group, and PNI-negative group. CT, computed tomography; LVI, lymphovascular invasion; PNI, perineural invasion; NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZ_{eff}, normalized effective atomic number; VMI (+), noise-optimized virtual monoenergetic images; A_{40}, attenuation value in enhanced VMI (+) at 40 keV−.

In our study, quantitative DECT parameters, including NIC, λ_{HU}, NZ_{eff}, and A_{40}, successfully predicted the histopathological features, and a combination of these parameters improved the predictive performance of the model. However, all the attenuation values (i.e., An, Ae, and ∆A) in PEI failed to predict these histological features. This may be because attenuation values in PEI are affected by a variety of variables, such as convolution kernels, reconstruction, artifacts, beam hardening, scanner linearity, and patient geometric features (46). Additionally, ∆A represents the attenuation value difference between the unenhanced and enhanced phases. A split-level image of these 2 phases due to a swallowing motion will result in inaccurate ∆A. IC directly captures the distribution of iodine contrast agent in tumor tissues. NIC is a standardized IC, which reduces individual differences in

perfusion and body weight and accurately reflects the blood perfusion status of tumors (47). This may explain why NIC can predict the pathological characteristics of HNSCC, but ∆A cannot.

HNSCCs are highly heterogeneous malignant tumors. Regardless of the pathological grade, the LVI status, and the PNI status, the CT features of HNSCCs may show heterogeneous density, ill-defined margins, the infiltration of adjacent structures, and high, medium, or low enhancement. Thus, the qualitative morphological analysis used in our work did not accurately characterize the histopathological heterogeneity of HNSCCs. Consistent with a recent study on nasopharyngeal malignancies (23), the morphological features failed to predict the histopathological characteristics in this study.

Our study had several limitations. First, while we

Figure 4 Quantitative parameters derived from dual-energy CT in patients with different histological features. (A-D) A 68-year-old man with grade III laryngeal squamous cell carcinoma and lymphovascular and perineural invasion. (E-H) A 55-year-old man with grade I laryngeal squamous cell carcinoma without lymphovascular and perineural invasion. (A,E) 40 keV VMI (+) in the contrast phase; (B,F) iodine maps; (C,G) effective atomic number maps; (D,H) the slope of the spectral Hounsfield unit curve. The NIC, λ_{HU}, NZ_{eff}, and A_{40} values of the first patient were higher than those of the second patient. VMI (+), noise-optimized virtual monoenergetic images; A_{40}, attenuation value in enhanced VMI (+) at 40 keV; CT, computed tomography; NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZeff, normalized effective atomic number.

Table 5 Performance of quantitative parameters derived from dual-energy CT in predicting histological features in patients with head and neck squamous cell carcinoma

Parameters	Tumor grade (G I, G II vs. G III)				Lymphovascular invasion				Perineural invasion			
	AUC	Cutoff value	Sensitivity	Specificity	AUC	Cutoff value	Sensitivity	Specificity	AUC	Cutoff value	Sensitivity	Specificity
NIC	0.841	0.234	80.0%	76.6%	0.812	0.234	77.8%	77.8%	0.824	0.234	83.3%	77.1%
λ_{HU} (HU/keV)	0.794	1.798	88.0%	66.0%	0.739	1.798	77.8%	62.2%	0.676	1.820	66.7%	60.4%
NZ_{eff}	0.793	0.806	80.0%	72.3%	0.770	0.807	74.1%	71.1%	0.794	0.814	70.8%	72.9%
A_{40} (HU)	0.769	195.850	72.0%	70.2%	0.715	190.240	77.8%	57.8%	0.690	195.850	62.5%	64.6%
Combined	0.969	−0.140	92.0%	95.7%	0.944	−0.625	92.6%	88.9%	0.931	−0.695	91.7%	85.4%

CT, computed tomography; NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZ_{eff}, normalized effective atomic number; VMI (+), noise-optimized virtual monoenergetic images; A_{40}, attenuation value in enhanced VMI (+) at 40 keV; Combined, combined NIC, λ_{HU}, NZ_{eff} and A_{40} by multivariate logistic regression analysis; AUC, area under the curve.

found significant correlations between the DECT parameters and the histopathological features known to be related to poor clinical outcomes, we did not find that the DECT parameters translated directly into clinical outcome parameters. Second, our study was a single-center study with no external validation. Third, the

HNSCC cases were selected from a heterogeneous group with malignancies in multiple head and neck areas from the oral cavity to the larynx. A study with a large sample size needs to be conducted to explore the ability of dual-energy CT to predict the histopathological features of tongue, oropharyngeal, hypopharyngeal, and laryngeal
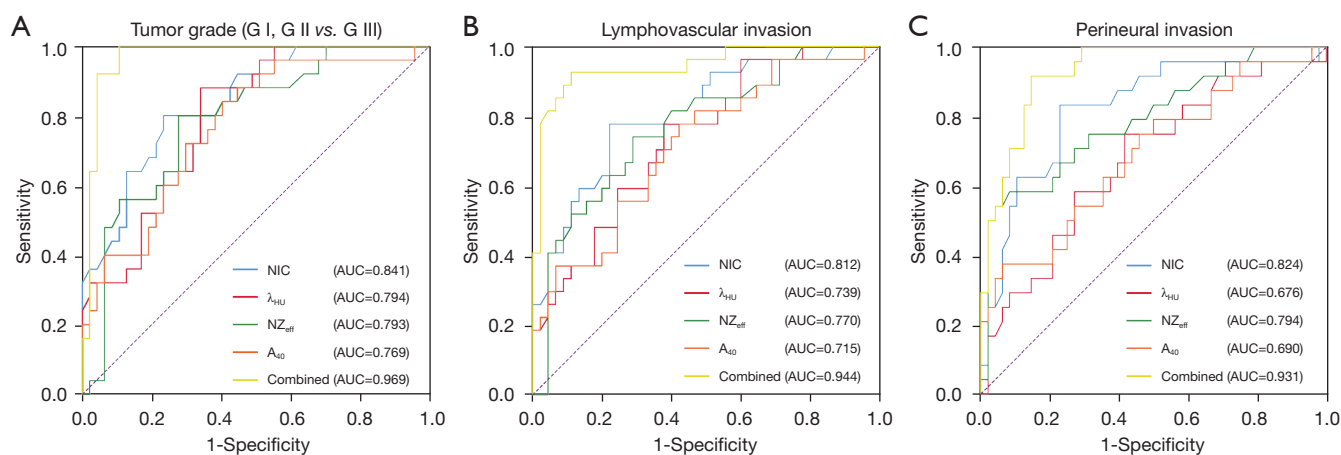

Figure 5 ROC analyses of quantitative parameters for predicting pathological features in head and neck squamous cell carcinoma. (A) (grade III *vs.* grade I and II), (B) lymphovascular invasion and (C) perineural invasion. The combination of NIC, λ_{HU}, NZ_{eff}, and A_{40} had the highest area under the curve value in comparison to any 1 parameter (all P values <0.05). NIC, normalized iodine concentration; λ_{HU}, slope of the spectral Hounsfield unit curve; NZ_{eff}, normalized effective atomic number; VMI (+), noise-optimized virtual monoenergetic images; A_{40}, attenuation value in enhanced VMIs (+) at 40 keV; ROC, receiver operating characteristic.

cancers. Fourth, the quantitative parameters were only obtained from axial slices of tumors but not from whole lesions. Finally, we did not compare the value of DECT in predicting the histopathological features of mucosal lesions and mass-like lesions due to the small sample size. However, we intend to analyze such lesions in a future prospective study with a large sample size.

In conclusion, quantitative parameters derived from pretreatment DECT, including NIC, λ_{HU} NZ_{eff}, and A_{40}, may serve as imaging markers for predicting the histopathologic characteristics of HNSCC, and a combination of all 3 quantitative parameters can improve the predictive performance of the model.

Supplementary methods: Image quality assessment of 40-80 keV VMIs (+) and PEI (M_0.4)

Subjective image quality assessment

Those 40-80 keV VMIs (+) and PEI data were independently analyzed by two radiologists with 10 and 20 years of experience in head and neck imaging interpretation, respectively. The evaluation of subjective image quality focused on overall image quality and demarcation of lesion margins. Overall image quality was classified using a 5-point Likert scale (1, unacceptable; 2, suboptimal; 3, adequate; 4, good; 5, excellent). Demarcation of lesion margin was classified using a 5-point Likert scale (ranging from 1 = no visual demarcation to 5 = perfect demarcation of contours).

Objective image quality assessment

Two radiologists (with 7 and 15 years of experience in head and neck imaging interpretation, respectively) blinded to any clinical information and pathological outcomes assessed the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) on the 40-80 keV VMIs (+) and PEI. Regions of interest (ROI) were placed on the following regions: primary tumor, right sternocleidomastoid muscle and pharyngeal air in contrast enhanced phase images, excluding any area of gross necrosis. Quantitative image quality was calculated as the following formulas:

$$SNR = HU_{primary\ tumor} / SD_{air}$$
$$CNR = (HU_{primary\ tumor} - HU_{right\ sternocleidomastoid\ muscle}) / SD_{air}$$

$HU_{primary\ tumor}$ and $HU_{right\ sternocleidomastoid\ muscle}$ are defined as the attenuation values of primary tumor and right sternocleidomastoid muscle, respectively. SD_{air} is defined as the standard deviation of attenuation values in pharyngeal air.

Figure S3 The Delong test results to compare these AUCs of quantitative parameters derived from dual-energy CT for predicting tumor grade (a), lymphovascular invasion (b) and perineural invasion (c).

Table S1 Subjective image quality assessment for 40-80 keV VMIs (+) and PEI (M_0.4)

Score	40keV	50keV	60keV	70keV	80keV	M_0.4	P value[†]
Overall image quality							
1	0	0	0	0	1	1	
2	0	0	1	16	18	23	
3	4	17	34	43	51	46	
4	26	36	19	5	2	2	
5	42	19	18	8	0	0	
Total	326	290	270	221	198	193	
Mean ± sd	4.5±0.6	4.0±0.7	3.8±0.9	3.1±0.9	2.8±0.5	2.7±0.6	<0.001
Demarcation of lesion margins							
1	0	0	0	0	0	0	
2	0	0	2	3	10	17	
3	0	16	24	37	50	39	
4	27	34	45	32	12	16	
5	45	22	3	0	0	0	
Total	333	294	271	245	218	215	
Mean ± sd	4.6±0.5	4.1±0.7	3.7±0.5	3.4±0.6	3.0±0.6	3.0±0.7	<0.001

Note. VMI (+) = noise-optimized virtual monoenergetic image; PEI (M_0.4) = 0.4-average-weighted polyenergetic images. [†]The One-way ANOVA with Bonferroni post hoc test.

Table S2 Objective image quality assessment for 40-80 keV VMIs (+) and PEI (M_0.4)

	40keV	50keV	60keV	70keV	80keV	M_0.4	P value[†]
SNR	27.24 (26.11–29.86)	22.48 (21.54–25.21)	19.06 (18.15–20.47)	14.36 (12.74–16.33)	12.28 (10.71–13.85)	12.00 (10.73–13.41)	< 0.001
CNR	11.27 (10.47–12.42)	8.76 (8.30–9.68)	7.02 (6.59–7.85)	4.24 (3.61–4.96)	2.02 (1.50–2.88)	2.00 (1.68 – 2.67)	< 0.001

Note. VMI (+) = noise-optimized virtual monoenergetic image; PEI (M_0.4) = 0.4-average-weighted polyenergetic images; SNR: signal contrast-to-noise ratio. CNR: contrast-to-noise ratio. [†]The Non-parametric Kruskal-Wallis with Bonferroni post hoc test.

Table S3 Morphological features on 40keV in HNSCC with different histological features

Morphological features	Tumor grade		P value	Lymphovascular invasion		P value	Perineural invasion		P value
	Grade I and II (n=47)	Grade III (n=25)		Negative (n=45)	Positive (n=27)		Negative (n = 48)	Positive (n = 24)	
Inhomogeneity density	33/47 (66.0 %)	22/25 (88.0 %)	0.082	34/45 (75.6%)	21/27 (77.8 %)	0.830	35/48 (72.9 %)	20/24 (83.3 %)	0.327
Ill-defined margins	21/47 (44.7 %)	17/25 (68.0 %)	0.054	21/45 (46.7 %)	17/27 (63.0 %)	0.180	23/48 (47.9 %)	15/24 (62.5 %)	0.243
Infiltration of adjacent structures	19/47 (40.4 %)	16/25 (64.0 %)	0.057	18/45 (40.0 %)	17/27 (63.0 %)	0.059	22/48 (45.8 %)	13/24 (54.2 %)	0.505
Degree of enhancement									
high	13/47 (27.7 %)	11/25 (44.0 %)	0.161	12/45 (26.7 %)	12/27 (44.4 %)	0.121	14/48 (29.2 %)	10/24 (41.7 %)	0.289
intermediate	27/47 (57.4 %)	11/25 (44.0 %)	0.277	25/45 (55.6 %)	13/27 (48.1 %)	0.542	28/48 (58.3 %)	10/24 (41.7 %)	0.182
low	7/47 (14.9 %)	3/25 (12.0 %)	0.735	6/45 (13.3 %)	4/27 (14.8 %)	0.860	7/48 (14.6 %)	3/24 12.5 %)	0.810
