Background: New evidence from retrospective cohort studies on risk of death from COVID-19 infection became available. We aimed to systematically review the clinical risk factors for fatal outcome of COVID-19. **Methods:** We performed meta-analysis, using PubMed, EMBASE and Cochrane databases from December 1 2019 to June 10 2020. The meta-analysis summarized clinical, laboratory, radiological features, and complications of non-survivors with confirmed COVID-19. In addition, a fixed- or random-effects model was adopted based on the heterogeneity among studies. We also used funnel-plot with Egger's tests to screen potential publication bias.

Results: In total, twenty studies with 15,408 COVID-19 cases were included in our meta-analysis. Male, current smoking, and older age were associated with in-hospital death. Patients aged 60 years or over had the highest pooled ORs [OR 4.94 (2.89, 8.44)]. Non-survivors were more likely to have diabetes, hypertension, cardiovascular disease (CVD), respiratory disease, or chronic kidney disease (CKD). Respiratory disease had the highest pooled ORs [OR 2.55 (2.14, 3.05)]. Dyspnea [OR 3.31 (1.78, 6.16); I²: 83%] and fatigue [OR 1.36 (1.07, 1.73); I²: 0%] were associated with increased risk of death. Increased white blood cell count, decreased lymphocyte and platelet counts, were also associated with increased risk of death. Biomarkers of coagulation function, inflammation, liver and kidney function, cardiac and muscle injury were also elevated in non-survivors.

Conclusions: Male, current smoking patients aged 60 years or over might face a greater risk of in-hospital death and the comorbidities such as diabetes, hypertension, CVD, respiratory disease, and CKD could also influence the prognosis of the COVID-19. Clinical feature such as dyspnea and fatigue could imply the exacerbation and even death. Our findings highlighted early markers of mortality which were beneficial to identify fatal COVID-19.

Keywords: COVID-19; SARS-CoV-2; risk factor; mortality

Introduction

Coronaviruses are vital pathogens that are distributed widely among humans and other animals which could cause enteric, neurologic, respiratory illness ranging from the common cold to fatal infections (1). The two highly pathogenic human coronaviruses—severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV)—are responsible for sometimes fatal diseases, SARS and MERS (2,3). The pandemic of coronavirus infectious disease-2019 (COVID-19), caused by the severe acute respiratory coronavirus 2 (SARS-CoV-2), have been one of the most serious challenge to global health systems (4).

Compared to SARS (10%) and MERS (30%), the case fatality rate (CFR) of COVID-19 is much lower which is estimated at 0.66% (0.39% to 1.33%) (5,6). However, many more deaths are caused by COVID-19 ultimately as it has rapidly spread across the world than did the others, owing to rapid human-to-human transmission and atypical symptoms with highly contagious in certain patients (7,8). In addition, the CFR is 30–70% for COVID-19 patients in intensive care unit (ICU) (9). Older patients with existing comorbidities have higher risk of death associated with COVID-19 (10).

Recently, numerous studies that have provided valuable data on demographic, clinical and laboratory features, complications, treatment and outcomes of inpatients with COVID-19, but the information is somewhat incomplete, part of them are low quality, and there are potential bias and residual confounding. Previous systematic review has merely integrated clinical and laboratory feature for nonsurvivors with COVID-19 from 4 Chinese studies (11). Many other important meta-analyses showed the risk factors of severity and mortality in COVID-19, including lab and imaging results (12-15), comorbidities (16-21) and medication use (22,23). But these reviews with limited sample size tended to combine the severity/critical patients with non-survivors leading to risk of bias. Tian et al. (24) reported COVID-19 patients with cardiometabolic disease and evidence for acute inflammation and end-organ damage are at higher risk of mortality. Although they included 14 studies, but patients enrolled in several studies were from the same hospital with time-overlapping which have potential bias and lead to unreliable results. By the same token, Parohan et al. (25) included studies which integrated information of deaths and critical/ICU patients. In addition, many of these studies were from pre-print datasets without peer-review. Due to limited articles available, their metaanalysis elucidated demographic feature and comorbidities of mortality. With an increased amount of studies published, we performed a more comprehensive meta-analysis about clinical, laboratory, radiological features, treatment and outcomes of non-survivors with COVID-19 which may help clinical physician make more sound decisions.

We present the following article in accordance with the PRISMA reporting checklist (available at http://dx.doi. org/10.21037/apm-20-1278).

Methods

The protocols of meta-analysis have been registrated in PROSPERO (CRD42020183514) (26).

Study selection and inclusion criteria

Our meta-analysis focus on the risk factors of mortality in patients with COVID-19. We searched PubMed, EMBASE and Cochrane carefully using keyword: "COVID*", OR "NCP*", OR "SARS-CoV-2", "coronavirus", OR "pneumonia", OR "nCoV", OR "HCoV", from December 1 2019 to June 10 2020. The search strategy was supplemented by retrieving medRxiv (https://www. medrxiv.org) and the references of included studies. Two investigators (GX and LX) independently evaluated search results and identified selected studies. Controversy was resolved by a third investigator (ZC). We follow Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement for conducting this meta-analysis (26).

We included studies met the following criteria: (I) hospitalized patients with confirmed COVID-19; (II) reported demographical, clinical feature, laboratory values, chest CT findings, treatment or outcomes of survivors and non-survivors respectively; (III) the risk factor of mortality; (IV) cross-sectional studies and (V) article language was English and/or Chinese. Studies which may enroll the same patients were evaluated by two reviewers and only one with priority was included. We also excluded studies without available data.

Data collection and quality assessment

Two investigators (GX and LX) extracted the following information for each identified study: (I) 1st author; (II) hospital; (III) sample size; (IV) demographic characteristics; (V) co-morbidities; (VI) clinical features; (VII) severity type; (VIII) laboratory and chest CT findings; (IX) complications; and (X) treatment and outcome (e.g., hospital length of stay). Primary outcome measure was to compare the demographic features, prevalence of co-morbidities and comorbidities between deceased and alive cases. Secondary outcomes were compared the incidence of symptoms and laboratory findings between deceased and alive subjects. Newcastle-Ottawa scale (NOS) was followed to assess the methodological quality (27). This scale has 11 evaluation criteria, including cohort representability, selection of non-exposed cohort, ascertainment of exposure, outcome not present at baseline, comparability of cohorts for important factors, comparability of cohorts for other variables, assessment of outcome, followup long enough for outcome to occur, adequacy of follow-up. We gauged each study on a scale of zero to 9 and considered studies with NOS score ≥ 6 as high quality. The checklist of the Agency for Healthcare Research and Quality (AHRO) was also used to assess the quality and bias risk of the included studies. This scale includes source of information, inclusion and exclusion criteria, time periods, consecutive subjects, mask of subjective components, quality assurance, explanation of exclusions, control of confounding factors, method of handling missing data, completeness of data collection, and follow-up. An item is scored as 1 if included in the article and 0 if not. A score of 8 or more is indicative of a high-quality study. Because no RCT investigating the risk factor of mortality was retrieved in our search, no quality assessment tool for RCTs was used in the current meta-analysis. Discrepancies were resolved by discussion in group conference.

Statistical analysis

We used odds ratios (OR) with 95% confidential intervals (CI) for categorical variables. In addition, continuous variables were compared by calculating mean differences (MD) or standardized mean difference (SMD), when applicable. The pooled results presented as forest plot using the fixed- or random-effect models. Publication bias was identified using funnel-plot and Egger's tests. Sensitivity or subgroup analyses were performed to handle heterogeneity. The meta-analyses were performed using Stata software version 15.1 (Stata Corp, College Station, TX, USA).

Results

Search result and study characteristics

We identified 3,833 studies and then excluded 571 duplicate articles. The remainder were sifted by 2 investigators (GX

and LX) who identified 731 articles relevant reports after reviewing titles and abstracts. Finally, 20 studies, including 1,970 non-survivors and 13,438 survivors, met our selection criteria and included (28-47). We excluded studies from the same hospital to avoid data duplication (Figure S1). The sample sizes among selected studies ranged from 19 to 8,910. Studies were conducted in Hubei [Wuhan (28-31,33-35,41-44) and Huanggang (32,33)], three continents (Asia, Europe, and North America) (36), New York (37,38), England (46), Italian (40,45) and Poland (39). Overall study quality, scored 6 to 9 according to the NOS and scored 8 to 10 according to the AHRQ, were considered high (*Table 1* and Table S1). Our study has language bias, because Chinese databases were not searched.

Demographical characteristics and comorbidities

In *Table 1* and *Figure 1*, we summarize the demographical characteristics and prevalence of comorbidities. The pooled results showed that sex [OR 0.66 (0.59, 0.73); I²: 29.3%], current smoking [OR 1.51 (1.23, 1.85); I²: 32.7%], and patients aged 60 years or over [OR 4.94 (2.89, 8.44); I²: 86%] were associated with fatal outcome. In *Figure 2*, we found an increased risk for mortality in patients with diabetes [OR 1.63 (1.44, 1.85); I²: 29.1%], hypertension [OR 2.26 (1.73, 2.95); I²: 77.4%], cardiovascular disease (CVD) [OR 2.52 (2.21, 2.89); I²: 49.6%], respiratory disease [OR 2.55 (2.14, 3.05); I²: 37.2%], chronic kidney disease (CKD) [OR 1.82 (1.46, 2.28); I²: 0%], and cancer [OR 1.43 (1.12, 1.82); I²: 37.1%].

None potential publication bias was found regarding mortality of COVID-19 in sex (P=0.202), diabetes (P=0.075), respiratory disease (P=0.610) and cancer (P=0.128), on the contrary in CVD (P=0.020), diabetes (P=0.038) and hypertension (P=0.007) with several studies beyond the 95% CI (Figure S2).

OR or HR values regarding the risk of in-hospital death were extracted from 8 studies. The OR values extracted from included articles were all unadjusted. We found that older age, male, and CVD were associated with increased odds of death (*Figure 3*).

Clinical manifestations and laboratory findings

In *Table 2*, we summarize the clinical manifestations. This meta-analysis showed that dyspnea [OR 3.31 (1.78, 6.16); I^2 : 83%] and fatigue [OR 1.36 (1.07, 1.73); I^2 : 0%] were associated with an increased risk for COVID-19 related mortality (*Table 3*).

Figure 2 Forest plots of underlying diseases in non-survivors vs. survivors.

2728

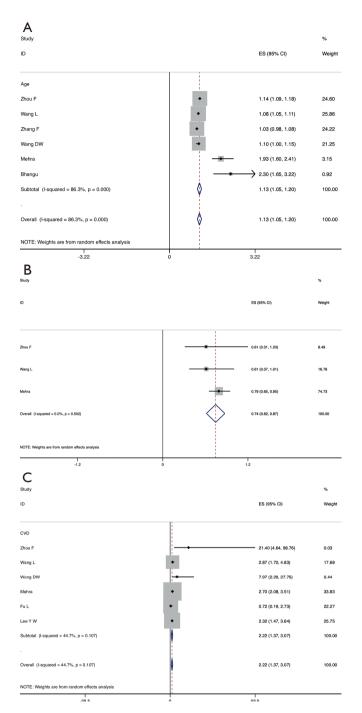

Figure 3 Forest plots of pooled OR regarding age (A), female (B), and cardiovascular disease (C).

creatinine, lactate dehydrogenase (LDH), and creatine kinase (CK). Decreased counts of lymphocytes [WMD -0.3 (-0.43, -0.17); I²: 92.8%], and platelet [WMD -34.8 (-50.88, -18.72); I²: 84%] were also associated with in-

hospital death.

Complications

The Table S2 shows the detailed summary comparing complications between non-survivors and survivors with COVID-19. The complications secondary to SARS-CoV-2 infection were more common in non-survivors including ARDS, sepsis, respiratory failure, heart failure, septic shock, acute cardiac injury, acute kidney injury and secondary infection compared to survivors.

Discussion

This study aimed to identify the risk factor of mortality associated with COVID-19. As we know, our meta-analysis included more patients with higher quality compared to previous meta-analysis (24,25). The results of this metaanalysis demonstrated that current smoking, male, aged 60 years or over might face a greater risk of in-hospital death and the comorbidities such as diabetes, hypertension, CVD, respiratory disease, and CKD could also influence the prognosis of the COVID-19. Clinical feature such as dyspnea or fatigue could imply the exacerbation. Our findings highlighted early markers of mortality which were beneficial to identify fatal COVID-19.

The course of SARS-CoV-2 infection can be broadly separated into three stages: first-stage, asymptomatic incubation period and virus may not be detected; secondstage, mild symptomatic period with detectable virus; finalstage, severe symptomatic stage, viral load is higher and the duration is longer (10,48). Around 15% of COVID-19 cases deteriorate to severe symptomatic phase, besides patients over 65 are more likely to develop severe illness (49). The question remained unresolved is why certain people progress severe disease and even die. Angiotensin-converting enzyme 2 (ACE2) receptor is a key target for SARS-CoV, and molecular modelling has indicated the structure of receptorbinding domains (RBD) of SARS-CoV and 2019-nCoV are strikingly similar (4). Though anchoring to the RBD, SARS-CoV-2 invade host cells especially in gastrointestinal, kidney, myocardial, and lung tissue leading to an exuberant immune response and enhanced cytokine release, named cytokine release syndrome (CRS), both contributed to multi-organ damage in severe COVID-19 patients (49).

Previous study reported that comorbidities could increase the mortality risk of SARS-CoV, and cardiac disease was strong predictor for adverse outcomes (50). Our findings

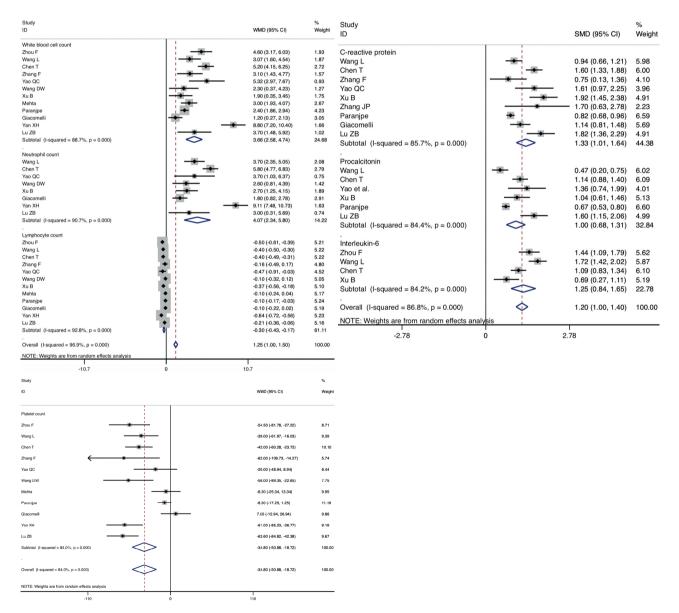

Figure 4 Forest plots of laboratory findings in non-survivors vs. survivors.

also indicated prevalence of comorbidities was higher in the deceased compared to the survivors, CVD could increase over 3-fold risk of death. Indeed, biomarkers of inflammation, liver and kidney function, cardiac and muscle injury were also elevated in non-survivors of COVID-19. We supposed that chronic inflammatory conditions caused by comorbidities such as CVD, diabetes, and hypertension has been aggravated leading to death by SARS-CoV-2 infection. Moreover, older age as risk factor of death probably because of weak immune system. Our findings are consistent with previous studies (51,52).

Pulmonary inflammatory response induced by S-protein of SARS-CoV-2 leading to alveolar damage, lung edema, compromised gas exchange, and progressive dyspnea. Prevalence of complications like sepsis, ARDS and shock were higher in non-survivors compared to survivors with COVID-19. Although the predominant complaint for COVID-19 patients was fever rather than dyspnea which is associated with 4-fold increase in the risk of death (53). The early recognition of dyspnea can help identify patients with poor prognosis. Interestingly, our meta-analysis showed that current smoking could increase about 2-fold risk of death. The reason, we speculate, may be that smoke could damage lung function, make it harder for infected patients to build up resistance to the virus and other diseases (54). In addition, males are more likely to smoke and suffer from chronic diseases which may contribute to mortality. We found thrombocytopenia, prolonged PT, and increased D-dimer in the deceased which is danger signal of DIC. In a multicenter study of 150 consecutive patients with COVID-19, Helms et al. (55) reported that plenty of COVID-19 patients developed ARDS had potentially fatal thrombotic complications. Anticoagulation should probably be suggested for critically ill patients with COVID-19. Rigorous randomized controlled trials are urgently needed to confirm these results.

Our review has limitations. This review can only provide results up to June 2020. However, we believe that new publications do not modify the trend and the main characteristics found for the disease. There was considerable heterogeneity in the data, which we interpret not to be due to major publication bias, or because of the heterogeneity of the disease itself. Moreover, evidence from early outbreaks and developing countries is limited duo to inadequate clinical treatment services resources. The present study is limited because of a focus on clinical factors only. These should guide us to pertinent questions for further study.

Conclusions

Our meta-analysis indicated that 60 years and older, male, current smoking, chronic complications, dyspnea or fatigue at illness onset, increased white blood cell count, neutrophils and IL-6 levels, lymphopenia, inflammation including increased CRP and PCT levels, liver and kidney dysfunction, cardiac and muscle injury, coagulation dysfunction including thrombocytopenia, prolonged PT, increased D-dimer level are important predictors for death in COVID-19 patients. In addition, patients who develop ARDS, sepsis, respiratory failure, heart failure, septic shock, and secondary infection have higher mortality risk.
