Abstract: Metastatic unresectable malignant melanoma (MM) owing to its intrinsic biological invasion potential and low sensitivity to radiochemotherapy has a poor prognosis and a high rate of mortality; the mean survival period is only 6–8 months, and the 5-year survival rate is less than 10%. The progression of patients with brain and liver metastases is worse than those with other distant or visceral metastases. With the advent of immunotherapy, especially immune-checkpoint inhibitors, long-term remission of stage IV disease may be achieved in some patients. Despite recent advances, not all patients benefit or can afford immunotherapy. Here, we report the case of a 44-year-old man whose initial diagnosis was MM with liver and multiple brain metastases. A high expression of F-box/WD repeat-containing protein 7 (FBXW7) inactivating mutation was observed, and the patient was treated with a combination of everolimus and temozolomide (TMZ) following palliative radiotherapy. The patient was stable for approximately 17 months, and eventually showed an overall survival (OS) of about 19 months. This case is novel and instructional, which highlights that the combination of everolimus and TMZ might be effective, with manageable toxicity, for advanced MM patients with FBXW7 mutation. And it may provide a reference for the treatment of analogous patients.

Introduction

Malignant melanoma (MM) is one of the most aggressive and therapy-resistant cancer that is derived from the melanocytes or cells developing from the melanocytes. The incidence of MM has risen dramatically. It is estimated that about 91,270 new individuals will be diagnosed with MM, and approximately 9,320 patients will die in 2018 (1). MM has a high propensity to metastasize to the distant lymph nodes, lungs, liver, bone, and brain (2). Once MM

metastasizes owing to its intrinsic biological invasion potential and low sensitivity to radiochemotherapy, prognosis is poor with a median survival of only 6 to 8 months. The progression of patients with brain and liver metastases is worse than those with other distant or visceral metastases (2,3). In the past decades, it was reported that more than one-third of patients with advanced MM have brain metastases at diagnosis, and up to 75% have brain metastases at the time of death (3). It has been shown that

Figure 1 Magnetic resonance imaging (MRI) of brain. (A) Multiple metastases of brain at the first diagnosis. (B) At post-radiotherapy assessment: sites of brain metastases were stable. (C) At the 17-month assessment: the brain metastases had significantly shrunk.

the median survival after WBRT was only 2–4 months. Liver metastasis may occur in approximately 50–80% of patients with advanced MM with a median survival time of only 2–6 months and a 1-year survival rate of 13% even after active treatment (4,5). Here, we report the case of MM with liver and multiple brain metastases. The patient was treated with a combination of everolimus and temozolomide (TMZ) that resulted in an unexpectedly prolonged survival. Our patient's outcome indicates that the combination of everolimus and TMZ could be a promising option for the clinical treatment of metastatic MM patients with FBXW7 mutation. We present the following case in accordance with the CARE reporting checklist (available at <http://dx.doi.org/10.21037/apm-20-1590>).

Case presentation

A 44-year-old Chinese man was admitted to the First Hospital of Jilin University for headache, vomiting, unstable gait, and declined hearing in his left ear visited our hospital 1 month in November 2016. Past medical history was as follows: three months ago, the patient underwent surgical excision of a progressively enlarged black patch with irregular borders in the occipital region of the scalp. However, no biopsy of the patch was performed after

surgery. No cancer history was identified in his family. The physical examination revealed hearing decline in his left ear without altered mental status and neurologic symptoms. The brain magnetic resonance imaging (MRI) scans showed multiple long T1 and T2 signals in the right forehead-temporal lobe, right caudate nucleus, left temporo-parietal lobe, corona radiata, left insular lobe, and bilateral basal ganglia without midline shift; some lesions showed significant inhomogeneous enhancement with gadolinium contrast (*Figure 1*). The abdominal computed tomography (CT) scans revealed the presence of a lesion sized 10.8 × 10.1 cm in the junction region of the left and right lobes of the liver and multiple lymphadenopathy in the hilar region (*Figure 2*). The carbohydrate antigen (CA)-125 levels increased up to 215 U/mL, and other serum tumor markers were within the normal range. Chest/pelvic CT scans and whole-body bone scintigraphy revealed no abnormal findings.

Following an ultrasound-guided percutaneous needle biopsy of the liver tumor, histopathology was performed. We observed epithelioid melanocyte proliferation with unclear cytoplasmic boundaries and hyperchromatic nucleus containing eosinophilic macronucleoli. Immunohistochemical analysis showed multifocal staining of melanocytic markers including S100, HMB-45, and Melan-A, which proved

Figure 2 Computed tomography (CT) and MRI of the abdomen. (A) An occupying lesion 10.8×10.1 cm in size in the junction region of left and right lobes of liver and multiple lymphadenopathy in hilar region; (B) at post-radiotherapy assessment: liver metastasis had slightly shrunk; (C) at the 17-month assessment: increase of liver metastases and development of pancreatic metastases.

that the tumor was an MM (*Figure 3*). Taken together, this patient was diagnosed as melanoma (stage IV) based on the 8th edition of the AJCC Cancer Staging Manual (1). After multidisciplinary consultation, the liver lesion and brain metastases were considered unresectable.

The patient underwent palliative radiotherapy (56 Gy in 25 fractions) for the liver metastasis and whole-brain radiotherapy (WBRT) (40 Gy in 20 fractions) with an integrated boost of 60 Gy for the brain metastases and was concomitantly treated with TMZ (75 mg/m² per day). The headache symptoms improved after radiotherapy. The brain MRI scans revealed that the metastatic sites were stable (*Figure 1B*). Abdominal CT scans showed a slight reduction in the volume of liver metastases (*Figure 2B*). No new metastases were identified. After obtaining informed consent from the patient, we performed a high-throughput

sequencing analysis of the liver biopsy specimens and identified a deleterious FBXW7 p.R505C mutation, where the FBXW7 protein was inactivated. The patient could not afford the expensive immune checkpoint inhibitors. Consequently, he received treatment with oral everolimus (10 mg/day) in combination with TMZ (150–200 mg/m² for 5 days every 28 days) starting from February 2017. The treatment was well tolerated, and the patient was generally asymptomatic but experienced inappetence and nausea. After 17 months, the brain MRI scan showed that the metastatic sites had significantly shrunk (*Figure 1C*); however, progression of liver disease and pancreatic metastases were detected in the abdominal MRI scan (*Figure 2C*). Everolimus and TMZ were suspended, and the patient received palliative treatment. The patient died 19 months after the initial diagnosis due to liver failure and

disease progression.

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee(s) and with the Helsinki Declaration (as revised in 2013). Written informed consent was obtained from the patient.

Discussion

We presented the case of an advanced stage MM male patient with liver and multiple brain metastases at the initial diagnosis, and the prognosis was poor. Treatment of patients with unresectable metastatic MM is challenging; systemic therapies or clinical trial is commonly recommended. The effectiveness of the use of multiple conventional cytotoxic agents both as monotherapy or combination therapy has been evaluated in the treatment of MM; however, no significant or limited survival benefit has been observed. Adding immunostimulatory cytokines, such as INF- α or IL-2, to traditional cytotoxic agents has also failed to improve the overall survival (OS), but has significantly increased toxicity (6).

TMZ is converted into dacarbazine *in vivo*. Compared with dacarbazine, TMZ has the advantages of oral administration, not being metabolized in the liver, and penetrating the blood-brain barrier (7). Compared with

TMZ alone, WBRT combined with TMZ may prolong the survival of patients with MM and unresectable brain metastases (8). Therefore, TMZ was used in combination with WBRT to alleviate the symptoms of this patient.

In the last few years, the OS of patients with metastatic MM has significantly improved with the development of personalized, targeted therapies [BRAF-V600 inhibitors, mitogen-activated protein kinase (MEK) inhibitors, and c-Kit inhibitors] and immune checkpoint inhibitors (anti-PD1 and anti-CTLA4 monoclonal antibodies) (9,10). High-throughput sequencing analysis of liver biopsy specimens revealed F-box/WD repeat-containing protein 7 (FBXW7) inactivating mutation; however, we did not detect other genomic mutations such as BRAFV600, MEK, or c-Kit mutations. Recent data revealed that FBXW7, a tumor-suppressor gene, encodes numerous F-box proteins. The F-box protein is a subunit of an E3-ubiquitin protein ligase complex named SKP1-cullin-F-box (SCFs), and is responsible for ubiquitination and degradation of several oncoproteins (11). The inactivating mutation of FBXW7 has been considered to be related to genetic instability, tumor proliferation, and metastasis (12). A study showed FBXW7 is a novel driver of a subset of melanoma, and this mutation was not associated with RAS or BRAF mutation (13). FBXW7 mediates the degradation of the mammalian target of rapamycin (mTOR), which plays a

major role in tumor proliferation, angiogenesis, protein synthesis, and cell cycle progression (14). Inactivating mutation of FBXW7 increases the levels of total and activated mTOR. Preclinical studies have shown that inactivating mutation of FBXW7 can predict sensitivity to mTOR inhibitors, which are used in the treatment of MM. In this case, the patient could not afford the expensive immune checkpoint inhibitors. The patient received a combination of everolimus and TMZ according to the test results. The treatment was well tolerated for about 18 months.

The rapid development of chemotherapy resistance is the main reason for treatment failure in advanced MM. mTOR inhibitor monotherapy has no or only a slight effect on melanoma cell growth (15). Recent research showed that mTOR inhibitors such as rapamycin and its derivatives, namely temsirolimus and everolimus, can enhance the chemosensitivity of metastatic MM to TMZ. TMZ has a synergistic effect on drug-induced tumor apoptosis and reduces VEGF secretion from the tumor cells, thereby inhibiting angiogenesis (16). Treatment with a combination of mTOR inhibitors and TMZ may increase the expression of prostate transmembrane protein androgen-induced 1 (PMEPA1), early growth response protein 1 (EGR1), and Dickkopf-1 (DKK1) in melanoma cells, and consequently, induce apoptosis (17). Sinnberg *et al.* (18) revealed that mTOR inhibitors partly suppressed myeloid leukemia cell differentiation protein-1 (Mcl-1), a member of the antiapoptotic Bcl-2 family; this enhanced chemosensitivity to TMZ and significantly inhibited the growth of the melanoma cells (up to 60%). A single-arm phase II multi-institution trial suggested that the combined treatment with everolimus and TMZ was well tolerated in patients with advanced MM. However, the median progression-free survival was 2.4 months and the median overall survival was 8.6 months, which failed to achieve its primary endpoint for promising clinical activity (19).

In conclusion, our case suggests that somatic gene mutation analysis of MM may give us a better understanding of the genetic changes in melanoma cells. FBXW7, a tumor-suppressor gene, is a potential novel driver for MM. Routine screening of MM for FBXW7 mutation may help to explore new therapeutic strategies for the patients. And the combination of everolimus and TMZ was well tolerated and effective in the treatment of a patient metastatic unresectable MM with FBXW7 inactivating mutation. The patient was stable for approximately 17 months and eventually survived for about 19 months after being

diagnosed with at an advanced stage. This is remarkable given that the mean survival period of patients with MM is only 6–8 months. Considering everolimus has multiple sensitizing effects on TMZ, everolimus combined with TMZ may be a viable treatment option for patients with metastatic MM patients and FBXW7 mutation. However, further investigation in more clinical trials into their use is needed.
